Classification Based on the Temperature Dependence of Cation Leaks
Other Disorders Characterized by Stomatocytosis
ACQUIRED DISORDERS OF RED CELL MEMBRANE LIPIDS
Spiculated Red Cells: Echinocytes and Acanthocytes
Spur Cell Anemia
Obstructive Liver Disease: Target Cells

During erythropoiesis the red cell membrane responds to erythropoietin and imports the billion or so iron atoms each red cell needs to complete hemoglobin synthesis. It sequesters the reductants required to protect hemoglobin and other cell proteins from corrosion by oxygen, and selectively retains other vital components such as organic phosphates, manufactured with precious adenosine triphosphate (ATP) energy, but it lets metabolic detritus escape. It even helps regulate metabolism by reversibly binding and inactivating many glycolytic enzymes.[1] In the circulation it carefully balances cation and water concentrations so red cells do not shrivel or burst. Simultaneously, it exchanges tremendous numbers of bicarbonate and chloride anions (≈10 to 30 billion/second/red cell), which aids transfer of carbon dioxide from the tissues to the lungs.[2] It also maintains a slippery exterior so that red cells do not adhere to endothelial cells or aggregate and clog capillaries. Finally, buttressed by the "membrane skeleton," a protein scaffold that lines the inner membrane surface, the membrane achieves the critical combination of strength and flexibility needed to survive four months in the circulation. Failure of any of these, or numerous other, functions shortens red cell survival, a process termed hemolysis. In fact, all hemolysis is ultimately due to membrane failure. This chapter will focus on inherited disorders of red blood cell membranes, particularly hereditary spherocytosis and hereditary elliptocytosis, the two most common and best understood diseases.

HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis (HS) (Table 16-1) is a common, inherited hemolytic anemia in which defects of spectrin

TABLE 16-1 Diseases in which Spherocytosis Is the Predominant Morphology[*]

Common Conditions
Hereditary spherocytosis
Immunohemolytic anemias (warm antibody type)
ABO hemolytic disease in neonates[†]
Uncommon to Rare Conditions
Hereditary stomatocytosis[†]
Hereditary cryohydrocytosis[†]
Clostridial sepsis
Hemolytic transfusion reactions
Severe burns and other red cell thermal injuries
Spider, bee and snake venoms[†]
Severe hypophosphatemia[†]
Acute red cell oxidant injury (e.g., glucose-6-phosphate dehydrogenase deficiency during hemolytic crisis, Wilson disease)[†]
Congenital dyserythropoietic anemia, type II[†]

[*] Some spherocytes may be seen in other diseases where they are not the predominant red cell morphology (e.g., hereditary pyropoikilocytosis, Heinz body hemolytic anemias, severe liver disease, microangiopathic hemolysis, hexokinase deficiency).

[†] Spherocytes are the predominant morphology in only a subset of patients.

or of proteins that attach spectrin to the membrane—ankyrin, protein 4.2, or band 3—lead to spheroidal, osmotically fragile cells that are selectively trapped in the spleen, resulting in a shortened red cell life span.

History

HS was first recognized more than 140 years ago by two Belgian physicians, Vanlair and Masius, who gave a remarkably thorough account of the disease.[3] They described a woman who suffered from the clinical symptoms now known as hallmarks of HS—anemia, jaundice, splenomegaly, and recurrent abdominal pain. The authors noted that most of the woman's red cells were spherical (Fig. 16-1) and hypothesized that a combination of splenic enlargement and liver atrophy led to their rapid destruction and the patient's anemia. They also noted that the patient's sister had suffered from an identical illness. In the 1890s, the British physicians Wilson and Stanley recognized the hereditary nature of the disease and were the first to note the characteristic pathologic appearance of the spleen engorged with red cells.[4,5] Subsequently, a report by Minkowski in 1900, in the German literature,[6] received wide attention, and many additional papers soon appeared, including Chauffard's classic description of osmotic fragility[7] and reticulocytosis[8] as hallmark laboratory features of the disease. The first successful splenectomy for HS was unintentionally performed by Wells in England 20 years before splenectomy became widely accepted[9] and 3 years before Wilson's description of HS appeared. While operating on a jaundiced woman for a supposed uterine fibroid, Wells encountered and bravely removed an enormous spleen. The patient recovered and her jaundice disappeared. Forty years after the splenectomy performed by Wells, Dawson[9] found the abnormal erythrocyte osmotic fragility during an examination of the woman and her son. The major clinical features of HS were defined by the 1920s, although nothing was known about the pathophysiology of the disease. Readers interested in more details about these and other aspects of the history of HS should consult the chapters by Dacie, Crosby, and Wintrobe in the wonderful book Blood, Pure and Eloquent.[10] Recent reviews of HS are also available.[11,12,13,14,15,15a]

Prevalence and Genetics

HS occurs in all racial and ethnic groups. It is particularly common in Europeans and their descendants in the New World. The classic estimate is that 1 person in 5000 is affected,[16] but this is almost certainly an underestimate. Surveys of red cell osmotic fragility suggest that mild forms of the disease may be four or five times more common than that.[17-19] In addition, testing of Swiss patients identified as having hyperchromic red cells on a routine complete blood count led to a diagnosis of HS in 1 of every 1700 individuals, most of whom were asymptomatic.[20] So the prevalence in Europeans is probably closer to 1 in 1500 to 1 in 2000. The disease is also common in Japan[21] and most other countries. Clinical experience suggests it is less common in African Americans and Southeast Asians.

HS exhibits both dominant and nondominant inheritance. About 75% of patients have typical autosomal dominant disease.[16,22-24] Homozygotes for dominant HS are very rare, with only a handful of reported cases.[23,25-28] The remaining 25% of HS patients show nondominant inheritance.[29,30] In these patients, both parents are clinically normal but some of them exhibit subtle laboratory abnormalities that suggest a carrier state.[22,30,31] The only available molecular survey suggests that the majority of nondominant HS patients have new dominant mutations, which tend to occur at CpG dinucleotides and are associated with small insertions or deletions.[29,30] This study suggests that true recessive HS is quite rare, perhaps less than 5% of the total,[30] but larger-scale studies are needed.

HS is caused by unique mutations in the membrane skeletal proteins ankyrin, β-spectrin, α-spectrin, band 3, and protein 4.2.

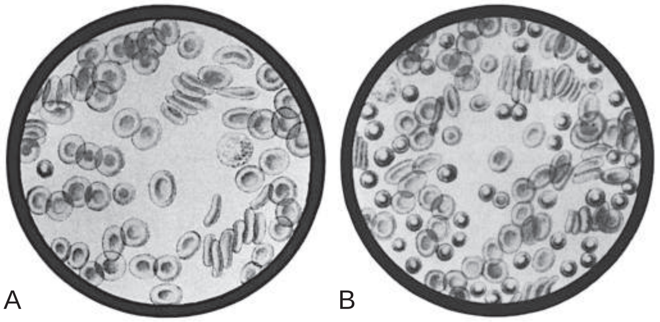

Figure 16-1 Lithograph of normal blood cells (**A**) and cells from a patient with "microcythemia" (**B**) described by Vanlair and Masius in 1871. This was the first description of hereditary spherocytosis. *(From De la microcythémie.* Bull R Acad Med Belg *5:515–613, 1871.)*

TABLE 16-2 Characteristics of Hereditary Spherocytosis

Clinical Features
Pallor
Splenomegaly
Intermittent jaundice
From hemolysis
From biliary obstruction
Anemic crises: hemolytic, aplastic or megaloblastic
Inheritance
Dominant ≈ 75%
Nondominant ≈ 25%
Rare manifestations
Leg ulcers
Chronic dermatitis
Extramedullary hematopoietic tumors
Angioid streaks
Spinocerebellar degeneration
Myocardiopathy
Excellent response to splenectomy
Laboratory Features
Anemia
Reticulocytosis
Spherocytosis
Elevated MCHC and elevated percentage of hyperchromic or hyperdense cells
Increased RDW (red cell distribution width, a measure of poikilocytosis)
Abnormality in one or more "HS tests"
Decreased band 3 (decreased fluorescence of red cells labelled with eosin-5′-maleimide)
Increased osmotic fragility (especially in the incubated osmotic fragility test)
Abnormal acidified glycerol lysis time or Pink test
Abnormal cryohemolysis test
Characteristic osmotic gradient ektacytometry profile
Normal Coombs (direct antiglobulin) test
Decreased red cell spectrin, or spectrin and ankyrin, or band 3 and protein 4.2, or absent protein 4.2 and decreased CD47

Clinical Presentation

Typical Hereditary Spherocytosis

The typical clinical picture of HS combines evidence of hemolysis (anemia, jaundice, reticulocytosis, gallstones, and splenomegaly) with spherocytosis and a positive family history (Table 16-2; Fig. 16-2). Mild, moderate, and severe forms of HS have been defined according to differences in various clinical and laboratory parameters under baseline conditions (Table 16-3).[13,22,32,33] Unfortunately, patients don't fit neatly into these categories: a person my be classified as "mild" by one criterion and "moderate" by another.[33a]

Initial assessment of a potential HS patient should include questions about neonatal or subsequent jaundice, anemia, splenomegaly, or gallbladder symptoms; transfusions; and a family history of these things and of splenectomies or cholecystectomies. The physical examination should seek signs of pallor, scleral icterus, and splenomegaly. Pediatricians should also examine the parents and siblings if they are present, particularly for splenomegaly, which is more evident in older patients. Scleral icterus is usually subtle and best perceived in daylight and at the edge of the conjunctivae (Fig. 16-3). Similarly, a spleen that cannot be palpated in a supine patient can sometimes be felt when the patient is placed on his or her right side with knees bent.

HS typically presents in infancy or childhood, but it may present at any age.[34] In children, anemia is the most common presenting complaint (50%), followed by splenomegaly, jaundice, or a positive family history.[35] No comparable data exist for adults. The majority of patients with HS have incompletely compensated hemolysis and mild to moderate anemia.[24] The anemia is often asymptomatic except for fatigue and mild pallor or, in children, nonspecific parental complaints such as irritability. Jaundice is seen at some time in about one half of patients,[24] usually in association with viral infections. When jaundice is present it is acholuric (i.e., unconjugated [indirect] hyperbilirubinemia without detectable direct bilirubinuria). Palpable splenomegaly is detectable in about one half of infants and most (70% to 95%) older children and adults.[24,35-37] Typically, the spleen is modestly enlarged (2 to 6 cm below the costal margin), but it may be massive.[38,39] There is no proven correlation between the size of the spleen and the severity of HS, although, given

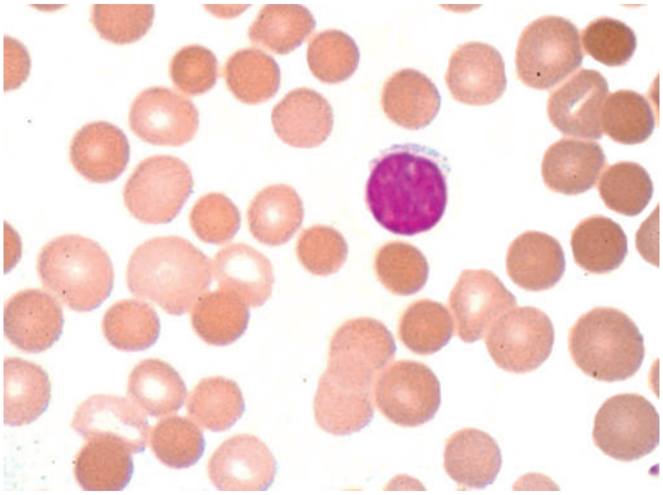

Figure 16-2 Peripheral blood smear from a patient with typical hereditary spherocytosis. Small, dense round microspherocytes are scattered throughout the smear, and most of the remaining, larger red cells have a smaller area of central clearing than normal.

TABLE 16-3 Clinical and Laboratory Classification of Hereditary Spherocytosis

	Normal	Mild Spherocytosis	Moderate Spherocytosis	Moderately Severe Spherocytosis	Severe Spherocytosis[*]
Inheritance	—	Autosomal dominant	Autosomal dominant, de novo mutation	Autosomal dominant, de novo mutation	Autosomal recessive
Proportion of hereditary spherocytosis cases	—	≈20% to 30%	≈60% to 70%	≈10%	<5%
Hemoglobin (g/dL)[†]	11.5-16[‡]	10.5-15	8-12	6-8	<6
Reticulocytes (%)[†]	0.5-1.5	1.5-6	≥6	≥10	≥10
Bilirubin (mg/dL)[†,‖]	0-1	0.5-2	≥2	≥2	≥3
Peripheral smear[†]	Normal	Mild spherocytosis	Spherocytosis	Spherocytosis	Spherocytosis ± poikilocytosis
Osmotic fragility (fresh)	Normal	Normal or slightly increased	Increased	Increased	Greatly increased
Osmotic fragility (incubated)	Normal	Usually increased	Increased	Increased	Greatly increased
MCHC (g/dL)[§]	32-36	34-37	34-38	35-39	
RDW (%)[§]	11-14	12-19	16-23	20-30	
Hb/MCHC[*]	0.38-0.41	0.35-0.40	0.29-0.33	0.18-0.28	
Hb/RDW[§]	0.95-1.05	0.7-1.0	0.48-0.74	0.16-0.35	
Serum transferrin receptor (nmol/L)[§]	18-25	30-65	80-125	100-150	
Erythropoietin (mIU/mL)[§]	7-16	9-30	25-90	30-300	
Membrane protein patterns (SDS-PAGE)[¶]	—	"Normal"[#] Slight ↓ spectrin Slight ↓ spectrin and ankyrin Slight ↓ band 3 and 4.2 Absent protein 4.2 and ↓ CD47	↓ Spectrin ↓ Spectrin and ankyrin ↓ Band 3 and protein 4.2 Absent protein 4.2 and ↓ CD47	↓ Spectrin ↓ Spectrin and ankyrin ↓ Band 3 and protein 4.2	↓↓ Spectrin ↓↓ Spectrin and ankyrin ↓↓ Band 3 and protein 4.2[**]
Transfusions	—	No	Sometimes required in infancy or with aplastic crisis	Occasionally with crises	Regular[*]
Splenectomy	—	Rarely, partial splenectomy[††]	Sometimes; consider partial splenectomy	Usually (6-9 years)	Yes (>3 years)

MCHC, Mean corpuscular hemoglobin concentration; *RDW*, red cell distribution width (measure of variation in shape); *SDS-PAGE*, SDS polyacrylamide gel electrophoresis; ↓, decreased.

[*] Patients with severe disease are transfusion dependent by definition. Values are in untransfused patients or at nadir before transfusion.

[†] *Data modified from Eber SW, Armbrust R, Schröter W: Variable clinical severity of hereditary spherocytosis: relation to erythrocytic spectrin concentration, osmotic fragility and autohemolysis.* J Pediatr *177:409–416, 1990.*

[‡] Varies with age.

[§] Ranges shown encompass the majority of individuals in each category. *From Rocha S, Costa E, Rocha-Pereira P, et al: Complementary markers for the clinical severity classification of hereditary spherocytosis in unsplenectomized patients.* Blood Cells Mol Dis *46:166–170, 2011.*

[‖] Multiply by 17.1 to convert to μmol/L.

[¶] Indicates common patterns observed on SDS gels. Decreased spectrin alone is seen in α-spectrin or β-spectrin defects. Decreased spectrin and ankyrin are observed with ankyrin defects. Decreased band 3 and protein 4.2 occur with band 3 defects. Absent protein 4.2 and decreased CD47 occur with protein 4.2 defects.

[#] Patients with mild spherocytosis who appear normal probably have small deficits (10% to 15%) that cannot be distinguished from normal findings on SDS gels.

[**] Rare patients with severe spherocytosis who are homozygous or compound heterozygous for band 3 defects.

[††] Consider in adolescents and adults who require a cholecystectomy or have disfiguring chronic jaundice.

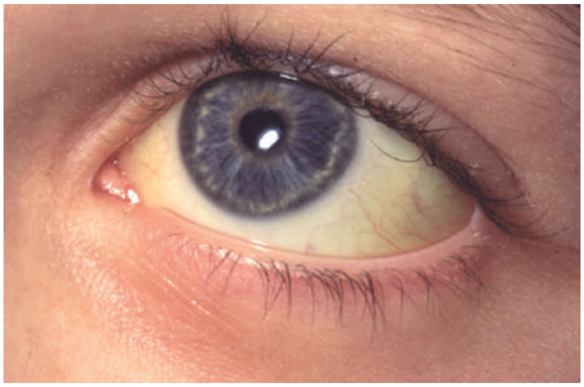

Figure 16-3 Scleral icterus in child with hereditary spherocytosis (HS). The jaundice in HS is often subtle and is more evident toward the posterior of the conjunctiva. *(From Bolton-Maggs P: Hereditary spherocytosis. Best Practice website, British Medical Journal Evidence Centre. BMJ Publishing Group Ltd. Accessed August 2013 at* http://bestpractice.bmj.com/best-practice/monograph/1143/resources/images/print/6.html.*)*

the pathophysiology and the response of the disease to splenectomy, such a correlation probably exists.

Typical HS is associated with both dominant and nondominant inheritance. The nondominant disease tends to be more severe, but there is considerable overlap.[22,29,31] Clinical severity and the response to splenectomy roughly parallel the degree of spectrin (or ankyrin) deficiency in patients with defects in either protein.[22,31,32,40-42] Disease in such patients can vary from mild to severe. Patients who are heterozygotes for band 3 defects have typical, moderate HS and moderate band 3 deficiency (15% to 35%).[42] Severe HS is rare in this population unless the patient carries two defective band 3 genes. Protein 4.2 deficiency is also associated with milder disease. Overall, patients with deficiency of spectrin or both spectrin and ankyrin have more severe disease than patients with band 3 or protein 4.2 deficiency,[24] but the differences are not great because true "severe" HS is rare.

In general, members of the same family will have a similar clinical picture, but there are exceptions, presumably due to varying compensation by the normal allele in patients who are heterozygous for a mutant gene, or by the coinheritance of another deleterious allele.[43-45] Such alleles should be sought in patients whose disease is much more severe than that of the rest of the family.

Silent Carrier State

The parents of patients with "nondominant" HS are clinically asymptomatic and do not have anemia, splenomegaly, hyperbilirubinemia, or spherocytosis on peripheral blood smears.[31] However, some have subtle laboratory signs of HS, including slight reticulocytosis (average, 2.1 ± 0.8%), diminished haptoglobin levels, slightly elevated osmotic fragility, or slightly shortened times in the acidified glycerol lysis test (AGLT).[22] Screening of normal Norwegian[17] and German[18] blood donors with the osmotic fragility test or AGLT showed a 0.9% to 1.1% incidence of previously unsuspected "very mild" HS. Presumably, some of these individuals were silent carriers of recessive HS genes, whereas others just had mild dominant HS. Unfortunately, no systematic molecular survey of this group of patients has been conducted.

Mild Hereditary Spherocytosis

Red cell production and destruction are balanced or nearly balanced in 20% to 30% of patients with HS.[24,36,46,47] These persons are considered to have "compensated hemolysis" and are usually asymptomatic. In some patients, the diagnosis may be difficult because hemolysis, splenomegaly, and spherocytosis are unusually mild. In this group of patients, reticulocyte counts are generally less than 6%, and only 60% of patients have obvious spherocytosis on peripheral blood smears.[22] About 10% of HS patients have very few (≤2%) or no detectable spherocytes.[24] In addition, red cell spectrin and ankyrin levels are typically more than 80% of normal.[22,42] As noted, many of these patients have band 3 or protein 4.2 defects.

Hemolysis may become severe with illnesses that cause splenomegaly, such as infectious mononucleosis.[48] Hemolysis may also be exacerbated by pregnancy[49,50] or exercise,[50] to the point where it may impair athletic performance in endurance sports. In many of these patients, HS is diagnosed during family studies or discovered when adult patients are diagnosed with splenomegaly or gallstones. Although mild HS is usually familial, it develops sporadically in families with more severe disease.[51] Presumably this is due to the coinheritance of modifying genes, such as those affecting spectrin or ankyrin synthesis or splenic function.

How to Explain "Compensated Hemolysis"

It is unclear why patients with HS and "compensated hemolysis" (i.e., normal hemoglobin levels) continue to have erythroid hyperplasia. Erythroid stimulation should disappear once hemoglobin levels reach normal if hemoglobin functions normally, as it does in HS. That it does not is shown by the fact that erythropoietin is inappropriately elevated (up to eight times normal) in HS patients with compensated hemolysis and no anemia,[33,47,52] and the fact that the serum transferrin receptor concentration, a measure of erythropoiesis,[53] is elevated.[42] The levels of 2,3-diphosphoglycerate (2,3-DPG) are reportedly low in hereditary spherocytes before splenectomy,[54] which could explain it; however the P_{50} of blood from HS patients is normal,[55] which does not make sense. A more likely possibility is that the dehydrated HS red cells are rheologically impaired and do not adequately perfuse the juxtaglomerular renal vessels, where erythropoietin is produced, even when the hematocrit is normal. If this hypothesis is correct, then erythropoietin production should correlate inversely with red cell deformability in any disorder where red cells are dehydrated (e.g., sickle cell anemia, hereditary xerocytosis). Clinically, the high level of erythropoietin and persistent erythroid hyperplasia in patients with HS and a normal hemoglobin level indicate that physiologically the patients are still anemic. *Indeed, it is possible that all HS patients are physiologically more anemic than their hemoglobin values suggest.*

Moderate and Severe Hereditary Spherocytosis

A small fraction of patients with HS (5% to 10%) have moderately severe to severe anemia. Patients with “moderately severe” disease typically have a hemoglobin value of 6 to 8 g/dL, a reticulocyte count of about 10%, a bilirubin level greater than 2 mg/dL, and 40% to 70% of the normal red cell spectrin content. The mean corpuscular hemoglobin concentration (MCHC) is high and the red cell distribution width (RDW) is very high (typically >20%) (see Table 16-3). Such patients are more susceptible to the dangers of hemolytic and aplastic crises (see later) and may occasionally need a transfusion. This category includes patients with both dominant and recessive HS and a variety of molecular defects in spectrin and ankyrin. Occasional patients with band 3 defects may fall into this category.

Patients with “severe” disease, by definition, have life-threatening anemia and are transfusion dependent. They often have recessive HS. Most of these patients probably have isolated, severe spectrin deficiency (<40% of normal) resulting from a defect in α-spectrin,[56] but some have ankyrin defects[42,57,58] or are homozygous or compound heterozygous for band 3 mutations.[28,43,44,59] Patients with severe HS are also distinguished by red cell morphologic findings. They often have some irregularly contoured or budding spherocytes and bizarre poikilocytes, in addition to typical spherocytes.[58-60] Such cells are rare before splenectomy in patients with less severe disease, although some may be seen after splenectomy. In addition to the risks of recurrent transfusions, patients with “severe” disease often suffer from an aplastic crisis and may develop growth retardation, delayed sexual maturation, or aspects of thalassemic facies.[38,39,60]

Hereditary Spherocytosis in Pregnancy

In general, unsplenectomized patients with HS have no significant complications during pregnancy except for anemia, which worsens because of plasma volume expansion[61] and sometimes because of increased hemolysis.[49,50] Hemolytic crises during pregnancy requiring transfusion have been reported.[50] Folic acid deficiency is also a risk.[62,63] One group reported that 20% of patients with HS received transfusions during pregnancy,[50] but in our experience, pregnant patients with HS rarely need transfusions.

Hereditary Spherocytosis in the Neonate

HS often presents as jaundice in the first few days of life.[24,64-67] Roughly one half of all patients with HS have a history of neonatal jaundice,[24,68] and 91% of infants discovered to have HS in the first week of life are jaundiced (bilirubin level >10 mg/dL).[66] In a French study of 402 jaundiced neonates requiring phototherapy, 1% were found to have HS.[69] Hyperbilirubinemia usually appears in the first 2 days of life and bilirubin levels may rise rapidly,[64,67,68] driven by the combination of hemolysis and the reduced capacity of the neonatal liver to conjugate bilirubin. Newborns with both HS and Gilbert syndrome, a common polymorphism in the promoter region of the uridine diphosphate–glucuronosyltransferase gene (UGT1A1) (see Chapter 4), develop neonatal jaundice more frequently[70] and may develop severe hyperbilirubinemia.[71] Kernicterus is a risk[64,65,71] and exchange transfusion or treatment with barbiturates are sometimes necessary, but in most patients the jaundice is controlled with phototherapy.

Only 43% of neonates with HS are anemic at birth (hemoglobin level <15 g/dL), and severe anemia is rare,[66] but those who present at birth tend to have a more severe course.[42] Most have a normal hemoglobin level at birth, which then decreases sharply over the first 3 weeks of life, leading to a transient, severe anemia.[72] In up to three fourths of HS infants, the anemia is severe enough to warrant transfusion or treatment with erythropoietin (see below). This anemia appears to be aggravated by an inability of the infant’s bone marrow to mount an appropriate erythropoietic response to anemia and to the development of splenic function.

Hydrops fetalis has been reported in a few patients and is associated with homozygosity or compound heterozygosity for spectrin or band 3 defects.[27,28,73] If hydrops fetalis is detected in utero, the fetus may require intrauterine transfusions. No instances of hydrops fetalis have been associated with ankyrin deficiency. Perhaps infants with ankyrin defects, similar to ankyrin-deficient *nb/nb* mice,[74] are partially protected in utero by the expression of ankyrin-related proteins in embryonic and fetal erythroblasts.

The diagnosis of HS is sometimes more difficult in the neonatal period than later in life. Splenomegaly is uncommon—at most the spleen tip is palpable—and reticulocytosis is variable and usually not severe.[67,68] Only 35% of affected neonates have a reticulocyte count greater than 10%.[66] In addition, the haptoglobin level is not a reliable indicator of hemolysis during the first few months of life.[75] An even greater problem is that 33% of neonates with HS do not have significant numbers of spherocytes on their peripheral blood smears.[66] Moreover, because fetal red cells are more osmotically resistant than adult cells when fresh and more osmotically sensitive after incubation at 37°C for 24 hours,[66,76] the osmotic fragility test occasionally gives false-positive (incubated) or false-negative (unincubated) results unless fetal controls are used. Fortunately, these results have been published,[66] and they appear to reliably differentiate neonates with HS, particularly when the incubated osmotic fragility test is used.[66,67] However, in our experience it is rarely necessary to use fetal controls. The standard osmotic fragility test usually suffices to make the diagnosis in conjunction with the blood smear, Coombs test, and other data. Tests such as the eosin-5′-maleimide–binding test, AGLT, Pink test, and cryohemolysis test and osmotic gradient ektacytometry (all discussed later) are more sensitive and specific than the osmotic fragility test in older children and adults, but they have not been systematically tested in the neonatal period. Studying the erythrocytes from the parents is also very useful in the diagnosis of HS, particularly if the infant has received a transfusion.[77]

However, it is clear that many infants with HS are not detected in the neonatal period on clinical grounds alone, even infants with hyperbilirubinemia,[78] probably because the disease is not considered or is not obvious. Ascertainment is greatly enhanced if all infants with a high MCHC and a high RDW are evaluated for HS.[78]

As noted above, some infants with HS become progressively more anemic in the first month or two of life and require transfusion. Fortunately, the problem is transient, except in rare patients with severe HS, and usually remits after one or two transfusions. Almost all infants with HS will outgrow the need for transfusion by the end of the first year of life.[72] If the child is otherwise well, we allow the hemoglobin level to fall to 5.5 to 6.5 g/dL before giving transfusions to try to stimulate the marrow and only raise the hemoglobin level to 9 to 11 g/dL after transfusion to avoid suppressing the desired marrow response.

Administration of recombinant human erythropoietin (rHuEpo) to infants with HS was beneficial in reducing blood transfusions in an uncontrolled, open-label study.[79] In this study, 13 of 16 infants given weekly subcutaneous injections of rHuEpo at a dosage of 1000 IU/kg had increases in the absolute reticulocyte count and hemoglobin values. The infants were given the same dosage of rHuEpo weekly based on their initial weight (at a range of initial ages from 16 to 119 days), a weekly hemoglobin level of less than 8 g/dL, and an absolute reticulocyte count of 200×10^9/L or less. Subsequent studies show similar effectiveness with different dosages and different frequencies.[80] Therefore erythropoietin therapy in infants with HS has become an alternative to transfusion, although weekly erythropoietin injections can be challenging for parents. Also, erythropoietin is twice as expensive as a single transfusion and erythropoietin-treated infants don't always avoid a transfusion.[80a] Further studies of recombinant erythropoietin therapy for neonatal anemia in HS are needed to determine the optimal time to initiate treatment, the optimal dosage, and the optimal duration of therapy.

Close observation of infants with HS is necessary to avoid complications of severe anemia. All infants with HS should have hemoglobin and reticulocyte measurements at least monthly during the first 6 months of life to avoid unnecessary side effects of severe anemia. The intervals may be increased thereafter, depending on the severity of anemia, but care must be taken to instruct parents on the signs and symptoms of an aplastic crisis.

Etiology: Membrane Protein Defects

The primary molecular defects in HS reside in membrane skeleton proteins, particularly the proteins whose *vertical* interactions connect the membrane skeleton to the lipid bilayer: spectrin, ankyrin, protein 4.2, and band 3 (Fig. 16-4). Because each of these proteins has more than one vertical attachment (ankyrin to RhAG as well as band 3, protein 4.2 to CD47 as well as band 3, spectrin to phospholipids and to the band 3 complex near actin), missense mutations that only impair a single protein-protein interaction are not pathologic, whereas reductions in the amounts of the four proteins are. In contrast, missense mutations predominate in hereditary elliptocytosis, which is caused by diminished *horizontal* interactions between

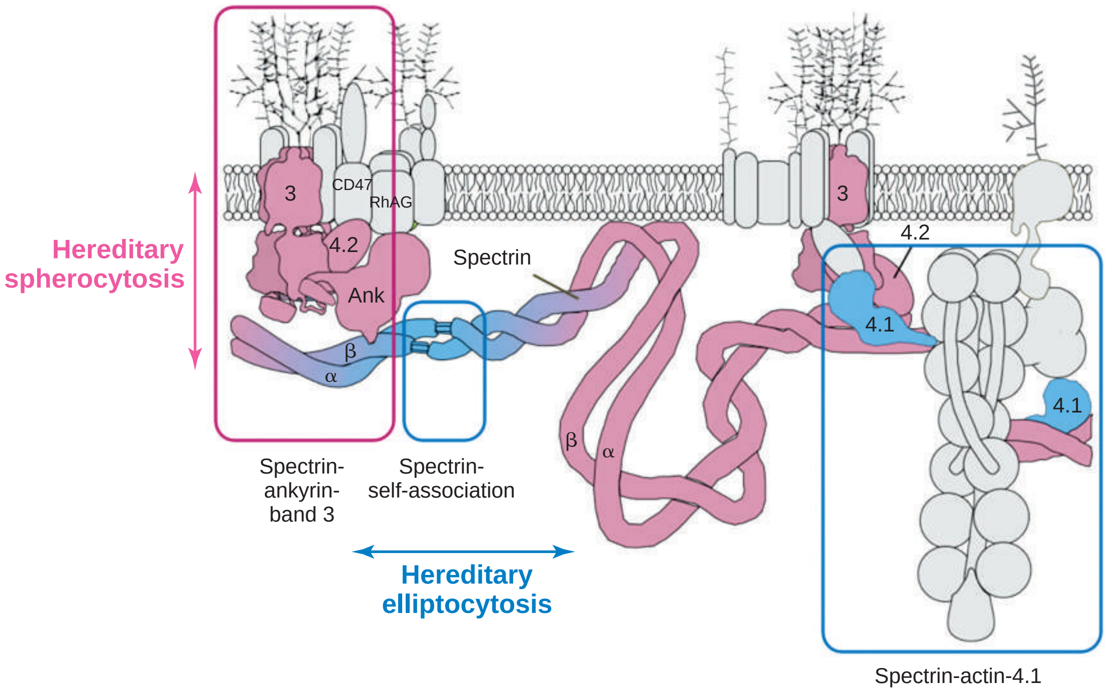

Figure 16-4 Membrane defects in hereditary spherocytosis and elliptocytosis. Hereditary spherocytosis is caused by a quantitative deficiency of spectrin, ankyrin, band 3, or protein 4.2, proteins involved in the "vertical" interactions that attach the membrane skeleton to the overlying lipid bilayer with its integral membrane proteins. Hereditary elliptocytosis is caused by functional defects in the "horizontal" protein interactions that hold the skeleton together. These are either defects near the head end of spectrin that impair self-association of spectrin dimers, or deficiency of protein 4.1R, a cofactor protein that bolsters the attachment of spectrin to actin. A more accurate model of the membrane is shown in Figure 15-6 of Chapter 15.

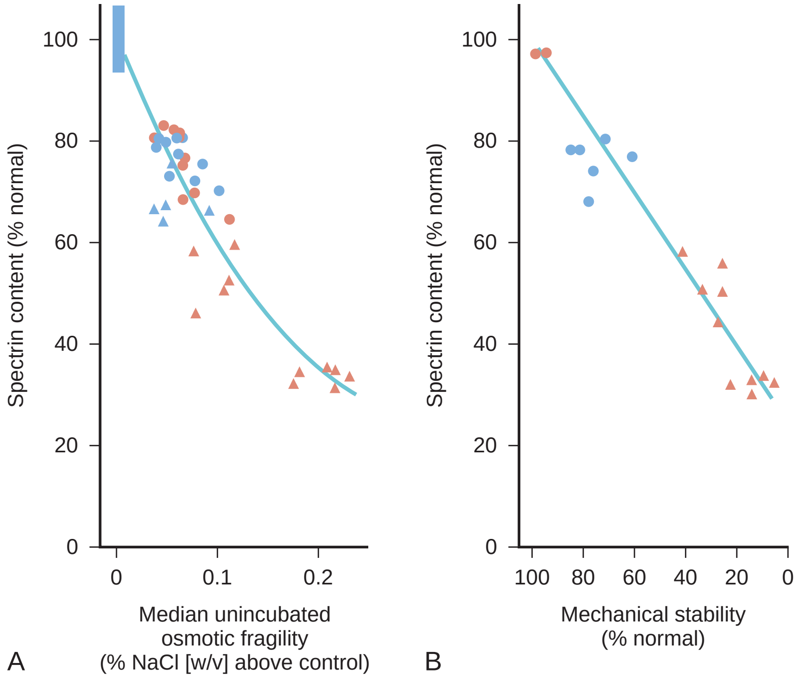

Figure 16-5 Correlation of spectrin content with (**A**) unincubated osmotic fragility and (**B**) mechanical stability in hereditary spherocytosis. *Circles* are patients with typical autosomal dominant hereditary spherocytosis. *Triangles* are patients with nondominant spherocytosis. *Reddish brown symbols* denote patients who have had a splenectomy. individual proteins that hold the membrane skeleton together, especially defects in spectrin self-association (see Fig. 16-4).

Patterns of Membrane Protein Deficiency in Hereditary Spherocytosis

Four patterns predominate: isolated, partial spectrin deficiency, seen with defects in α-spectrin or β-spectrin; combined, partial spectrin and ankyrin deficiency, seen with primary ankyrin defects; combined, partial band 3 and protein 4.2 deficiency, seen with defects in band 3; and nearly complete loss of protein 4.2 and CD47, seen in primary defects of protein 4.2. In Europeans and Americans ankyrin and band 3 defects are most common, roughly 45% and 30%, respectively; β-spectrin defects account for perhaps 20%. Protein 4.2 and α-spectrin defects are both recessive and are rare. However, the pattern of membrane protein defects varies in different populations. In Japan, deficiencies of band 3 and protein 4.2 are the most common forms of HS.[21] In Korean patients, ankyrin and spectrin defects are most common, but protein 4.2 deficiency occurs more often than in European or American patients.[81]

Because most mutations are unique within each family and the mutation itself does not usually predict the phenotype, it is rarely clinically useful to determine the specific molecular defect in patients with HS. Readers who are interested in tables listing many of the mutations described to cause HS should consult lists in various chapters and reviews,[82-85] including the previous edition of this text,[86] or one of the two versions of the Human Gene Mutation Database: HGMD Professional,[87] a subscription database that is available through many medical libraries, and the public version of HGMD,[88] which is free but lags 3 years behind the subscription version.

For patients whose red cells are spectrin deficient, the degree of deficiency correlates well with the spheroidicity of HS red cells, the severity of hemolysis, and the response to splenectomy (Fig. 16-5, *A*).[22,31,89] The mechanical properties of the cells, particularly their ability to withstand shear stress, also correlate with their spectrin content (see Fig. 16-5, *B*).[89,90] Microscopically, HS red cells with spectrin deficiency show fewer spectrin filaments interconnecting spectrin–actin–protein 4.1R junctional complexes, but overall skeletal architecture is preserved,[91] except in the most severe forms of the disease.

α-Spectrin Defects: Recessive Hereditary Spherocytosis

In humans, α-spectrin synthesis exceeds β-spectrin synthesis by about four to one.[92] Heterozygotes for α-spectrin synthetic defects still produce enough normal α-spectrin chains to pair with all of the β chains that are made. Thus α-spectrin defects are only apparent in the homozygous or compound heterozygous state and exhibit recessive inheritance. Moreover, there may only be a limited spectrum of mutations that cause clinical disease. Production-defective or “thalassemia-type” mutants that only moderately affect expression, such as α-spectrin$^{\text{LELY}}$ (to be discussed under hereditary elliptocytosis), have no

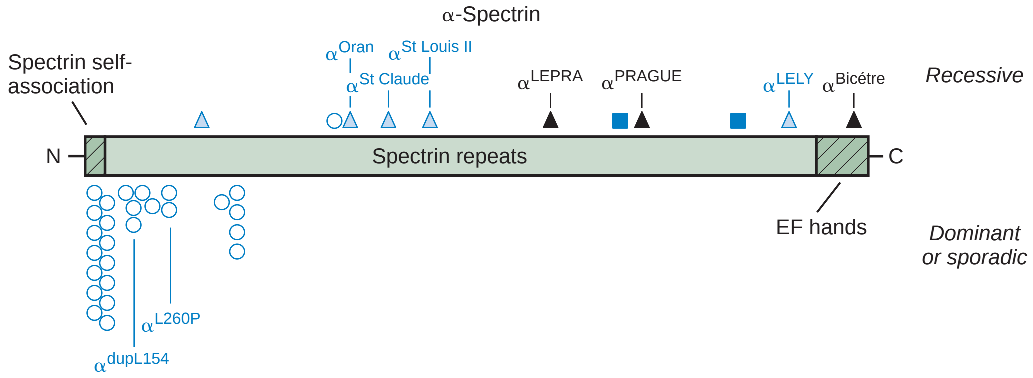

Figure 16-6 α-Spectrin mutations in hereditary spherocytosis (HS; *black*) and hereditary elliptocytosis (HE; *blue*). Missense mutations and in-frame insertions and deletions are indicated by *circles*. Splicing mutations that abolish or nearly abolish α-spectrin expression are indicated by *solid triangles*. Splicing mutations that partially decrease expression are indicated by *shaded triangles*. Note that HE mutations cluster near the N-terminus and tend to be amino acid substitutions that impair function (spectrin self-association), whereas HS mutations are defects that greatly decrease α-spectrin expression. The HS mutations are recessive because α-spectrin synthesis exceeds β-spectrin by a factor of 3 to 4, so that the expression of both α-spectrin genes must be greatly impaired to cause disease. α^{LELY} is a very common polymorphism of α-spectrin that diminishes synthesis by about 50% (see section on hereditary elliptocytosis).

phenotype, even in the homozygous state. Based on the few reported cases, it appears that the output of the α-spectrin gene must be less than 25% of normal to cause disease and may be as low as 8% of normal and still be compatible with life.[93] No homozygous null mutations have been reported, so it is possible they are lethal in the embryo.

To date, only 2% of all the mutations reported to cause HS involve α-spectrin (Fig. 16-6). Wichterle et al[94] reported a patient with severe HS who was a compound heterozygote for two different α-spectrin gene defects: in one allele, there was a splicing defect associated with an upstream intronic mutation, α^{LEPRA} (low-expression allele Prague); in the other allele, there was a null mutation, α^{PRAGUE}. The α^{LEPRA} allele produces one-sixth as much correctly spliced α-spectrin mRNA as normal. It is a relatively common allele, estimated to be 5% among Caucasians,[11] and is in linkage dysequilibrium with $\alpha^{Bughill}$, which is an innocent amino acid polymorphism (Ala970Asp).[56] Delaunay reported a similar family combining $\alpha^{LEPRA}/\alpha^{Bughill}$ on one chromosome with a double mutant $\alpha^{LELY}/\alpha^{Bicêtre}$ on the other, where the latter mutation essentially abolished α-spectrin output.[93] In both cases the combination of the severely impaired α^{LEPRA} allele with a null mutation of α-spectrin in *trans*, leads to significant, spectrin-deficient spherocytic anemia. As expected, even in the most severe forms of α-spectrin–linked recessive HS, obligate heterozygotes are asymptomatic and have little or no spectrin deficiency.[31,40,60]

Clinical Features. Less than 5% of patients with HS have primary defects in α-spectrin, but most of those patients have severe HS. Their red cells only contain 25% to 50% of the normal amount of both spectrin chains (Table 16-4).[31,40,60] Many are transfusion dependent, and even after splenectomy they may experience only a partial recovery. Blood smears are more bizarre than is typical for HS and show intense spherocytosis and irregular contracted cells (Fig. 16-7, *A*).

β-Spectrin Defects: Dominant Hereditary Spherocytosis

β-Spectrin synthesis limits formation of $\alpha\beta$-spectrin heterodimers, so even modest defects in the expression of β-spectrin are apparent in the heterozygous state and exhibit a dominant pattern of inheritance. Of the reported HS mutations 17% are in β-spectrin,[87] a finding that fits with the general impression that β-spectrin defects account for 15% to 25% of cases. Some groups report a much higher proportion of HS patients with isolated spectrin deficiency when sodium dodecyl sulfate (SDS) gels are used for membrane protein analysis, but that may reflect problems with assessing ankyrin deficiency on SDS gels (see later). The characteristics of HS due to β-spectrin deficiency are listed in Table 16-5.

The described mutations in β-spectrin include initiation codon disruptions, frameshift and nonsense mutations, gene deletions and rearrangements, and splicing defects (Fig. 16-8). Most patients have defects that impair or abolish β-spectrin production from the affected allele. All of the β-spectrin is generated from the normal allele

TABLE 16-4 Hereditary Spherocytosis Due to α-Spectrin Mutations
<5% of hereditary spherocytosis
Autosomal recessive since four-fold more α-spectrin is made than β-spectrin
A low expression, “thalassemia-type” defect in α-spectrin is often paired with a second presumably null allele on the opposite chromosome (in *trans*). The combination must reduce α-spectrin expression by at least 75% to impair $\alpha\beta$-spectrin assembly enough to cause HS. Homozygous null mutations may be lethal
Severe hemolysis and anemia, often transfusion dependent
50%-75% spectrin deficiency in red cells
Red cell morphology not well defined but dense, irregular poikilocytes as well as spherocytes in some patients

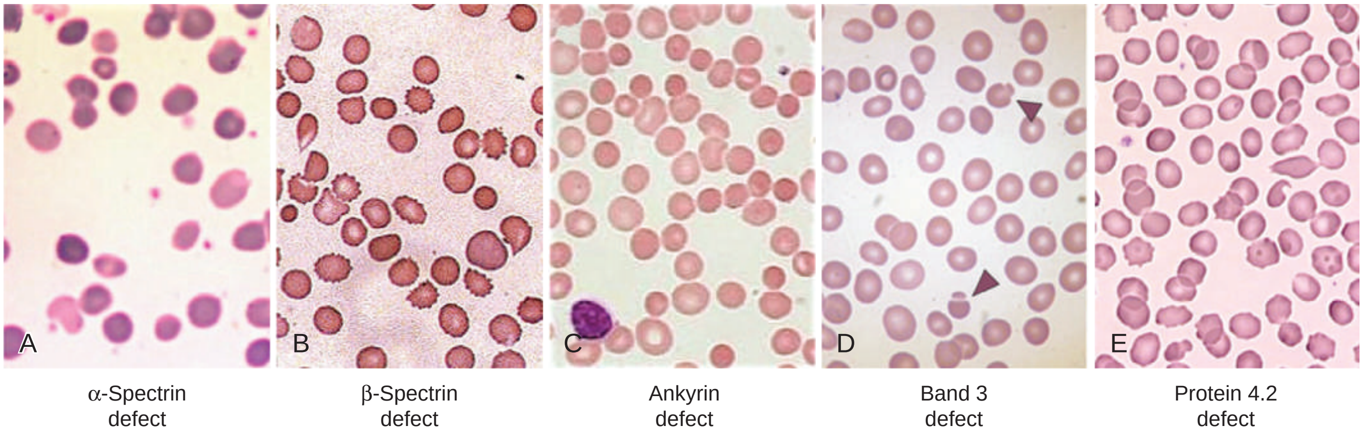

Figure 16-7 Red cell morphologic findings in hereditary spherocytosis (HS). **A**, Severe HS due to a homozygous α-spectrin defect. The spherocytosis is intense, and some cells have an irregular shape. Few cells have any central pallor. **B**, HS due to a heterozygous β-spectrin null mutation. Echinocytes and acanthocytes (5% to 15%) are often observed in addition to typical spherocytes. **C**, Heterozygous ankyrin-deficient HS. Typical microspherocytes are evident among red cells with some central pallor. **D**, Heterozygous band 3–deficient HS. A few button mushroom–shaped (or "pincered") red cells *(arrowheads)* are found in about 80% of patients with this form of HS. **E**, HS due to a homozygous protein 4.2 defect and nearly complete lack of the protein. Red cell morphologic findings are variable in this form of HS and, as here, there may be relatively few spherocytes. Echinocytes, slightly elongated elliptocytes (ovalocytes), stomatocytes, and other poikilocytes may be seen. *(A and E, From Delaunay J: The molecular basis of hereditary red cell membrane disorders.* Blood Rev *21:1–20, 2007; D, from Bolton-Maggs P, Crary S:* Hereditary spherocytosis. *Epocrates Online. TABLE 16-5 Hereditary Spherocytosis Due to β-Spectrin Mutations

15%-25% of hereditary spherocytosis cases
Almost all individual, dominant null mutations
Spectrin content decreased 15%-40%
Mild to moderately severe anemia
Blood smear with spherocytosis plus 5%-15% spiculated red cells in most patients
Spherocytosis plus elliptocytosis (i.e., spherocytic elliptocytosis) in some patients with C-terminal mutations that impair spectrin self-association *and* decrease spectrin content

in *trans*, which compensates to varying degrees, so that the red cell spectrin content is only decreased by 15% to 40% instead of the expected 50%. This suggests that β-spectrin is also synthesized in excess, though much less so than α-spectrin. The degree of compensation probably accounts for much of the variation in clinical severity among patients with β-spectrin HS.

Patients with deletions of the whole β-spectrin locus,[95] or with gross rearrangements,[96] also have autism[95] and learning disabilities,[96] indicating that genes close to β-spectrin on chromosome 14 are involved in cognition. There are HS patients with potentially instructive missense mutations, including a group clustered in the actin

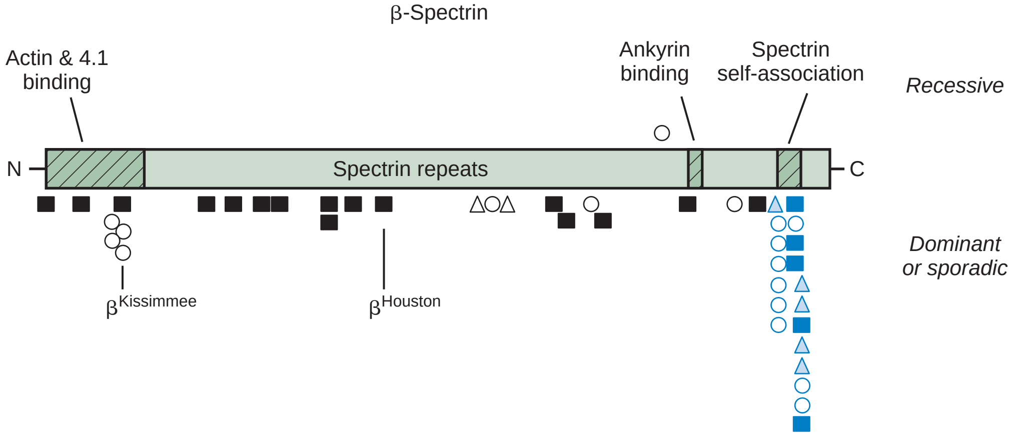

Figure 16-8 β-spectrin mutations in hereditary spherocytosis (HS; *black*) and hereditary elliptocytosis (HE; *blue*). Missense mutations and in-frame insertions and deletions are indicated by *circles*. Nonsense and other null mutations are indicated by *squares*. *Partially shaded triangles* denote splicing mutations that decrease but do not abolish expression. Patients with deletions of the whole β-spectrin locus[95] and with gross rearrangements[96] are also known but are not shown here. Note that HE mutations cluster near the C-terminus of β-spectrin and impair function (spectrin self-association) by altering amino acids or prematurely terminating the peptide chain. In contrast, most HS mutations abolish expression of the affected β-spectrin allele.

and protein 4.1R binding domain (spectrins Atlanta,[97] Kissimmee,[98,99] and Oakland[97]) and in the spectrin repeat domain (spectrins Columbus,[97] Birmingham,[97] and Sao Paulo[85]). It would be interesting to know whether these amino acid substitutions cause HS because they impair a specific function or whether the missense mutations simply destabilize β-spectrin and act like null mutations. In the case of spectrin$^{\text{Kissimmee}}$ (Trp202Arg), which is the only mutation where function was examined, both things were true. The mutant protein lacked the ability to bind protein 4.1R and, as a consequence, bound poorly to actin,[98] but it was also unstable and decreased in amount.[98,99]

All of the reported defects of β-spectrin are limited to single families with the exception of spectrin$^{\text{Houston}}$, a null mutation that has been found in several unrelated kindreds.[97]

Clinical Features. Patients with HS caused by β-spectrin mutations have hemolysis and anemia that vary from mild to moderately severe (see Table 16-5). Interestingly, in HS patients in whom peripheral blood morphologic characteristics have been described, those with β-spectrin mutations have had a small population (5% to 15%) of acanthocytes or spiculated spherocytes (spheroechinocytes) as well as spherocytes (see Fig. 16-7, *B*).

Ankyrin Defects

Spectrin heterodimers are only stable when bound to the membrane, and ankyrin, the high-affinity binding site, is normally present in limiting amounts. As a result, ankyrin defects are typically expressed as a dominant defect, although recessive mutations have been described. Ankyrin mutations are estimated to account for 30% to 60% of HS cases in Northern European populations and 5% to 10% of HS cases in Japan. Of all the known HS mutations, 35% are Ank1 defects.[87] The characteristics of HS due to ankyrin defects are listed in Table 16-6.

A role of ankyrin in HS was initially suggested by two patients with an atypical, unusually severe form of HS characterized by bizarre-shaped microspherocytes and red cell spectrin and ankyrin levels that were only 50% of normal.[58] Ankyrin synthesis was half normal; spectrin synthesis was normal, but only 50% of the synthesized spectrin attached to the membrane, presumably owing to the lack of ankyrin sites.[41] These results were the initial indication that ankyrin deficiency or dysfunction leads to concomitant spectrin deficiency in HS.

Additional studies showed that ankyrin deficiency is common in typical, dominant HS. When measured by radioimmunoassay, red cell membrane spectrin and ankyrin levels were less than the normal range in a large fraction of American kindreds, and the two proteins were proportionally decreased in nearly all the deficient kindreds.[100] Similar data have been obtained in multiple populations.[32,81,101-105]

Genetic analyses supported the hypothesis that a defect of the ankyrin gene could cause HS. Initially, studies of atypical patients with HS and karyotypic abnormalities, including translocations and interstitial deletions, defined a locus for HS at chromosomal segments 8p11.2-21.1.[106-110] After the ankyrin gene was cloned, it was localized to this same region, 8p11.2.[106] Fluorescence-based in situ hybridization of metaphase spreads from a patient with HS and an interstitial deletion of chromosome 8p11.1-p21 provided direct evidence that one copy of the erythrocyte ankyrin gene was deleted.[106] Ankyrin content in the patient's red blood cell membranes was reduced by 50%. Gene mapping then linked ankyrin to HS in a large family with typical dominant HS.[111] Further studies showed that ankyrin mutations are common in HS[57] and that many HS patients express only one of their two ankyrin alleles.[112]

Ankyrin mutations occur in both dominant and nondominant HS. Frameshift and nonsense mutations, which abolish the normal ankyrin product, are particularly common in dominant HS (Fig. 16-9). They produce mild to moderately severe hemolytic anemia, depending on the output of the remaining normal ankyrin gene and, perhaps, other modifier genes. For example, ankyrin$^{\text{Marburg}}$ and ankyrin$^{\text{Einbeck}}$ are frameshift mutations that occur in the NH_2-terminal (membrane) domain. Neither produces a detectable product in mature red cells. They would be expected to have a similar phenotype, but patients with ankyrin$^{\text{Einbeck}}$ have very mild disease and normal ankyrin levels, whereas patients with ankyrin$^{\text{Marburg}}$ have moderate to severe HS and moderate ankyrin deficiency (64% of normal). Understanding such phenotypic variations is one of the critical issues in HS research.

The most common ankyrin variant in patients with recessive HS is a T→C nucleotide substitution in the ankyrin gene promoter −108 bp from the translation start site. The allele occurs in 29% of German HS patients and 3% of normal individuals.[57,113] It is usually in *cis* with a G→A nucleotide substitution 153 bp from the start site[114] and impairs ankyrin synthesis in transgenic animals.[115] A −72/73 dinucleotide deletion in the ankyrin promoter also impairs expression by disrupting the recognition site for the TATA-binding protein and interfering with transcription initiation.[116] These "thalassemia-like" promoter mutations are silent in obligate heterozygotes; thus patients with nondominant HS must have a second mutation.[114] The promoter mutations aggravate ankyrin mutations if

TABLE 16-6 Hereditary Spherocytosis Due to Ankyrin Mutations

30%-60% of hereditary spherocytosis in the United States and Europe; 5%-10% in Japan
Autosomal dominant and autosomal recessive
Dominant mutations are mostly null mutations and are nearly all unique
Recessive mutations are missense and promoter defects: −108T→C promoter mutation is common
Both spectrin and ankyrin are equally decreased by 15%-50%
Mild to moderately severe anemia. Occasionally causes severe disease
Blood smear shows spherocytosis without other abnormal morphology

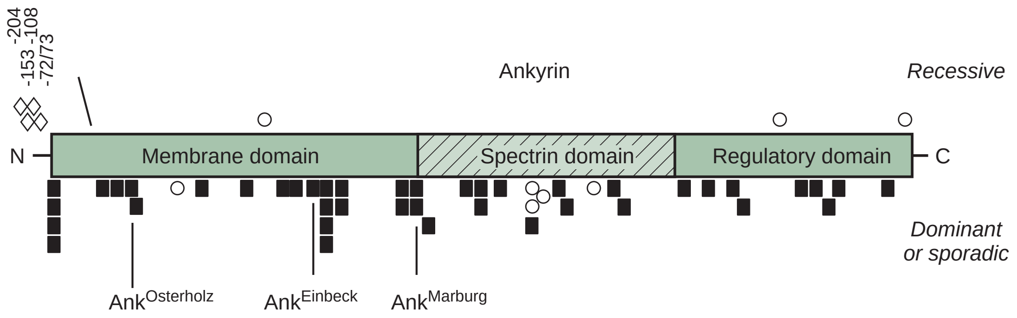

Figure 16-9 Ankyrin mutations, all of which cause hereditary spherocytosis (HS; *black*). Missense mutations and in-frame insertions and deletions are indicated by *circles*. Nonsense and other null mutations are indicated by *squares*. Four mutations in the 5′-untranslated region that are believed to decrease expression are indicated by *diamonds*. Note that the majority of mutations are dominant and abolish expression of the affected ankyrin allele.

they are inherited in *trans*, on the "normal" allele, particularly the −108 mutation, which is relatively common. For example,[116] in a family with ankyrin$^{\text{Osterholtz}}$, which is a null mutation,[57] the daughter, who has a combination of ankyrin$^{\text{Osterholtz}}$/ankyrin$^{-72/73}$, has more severe disease than her mother, who only carries ankyrin$^{\text{Osterholtz}}$.

Patients with gene deletions[106-110] involving the ankyrin locus at 8p11.2 often have features both of HS and Kallmann syndrome (hypogonadotrophic hypogonadism, type 2, due to FGFR1 defects) because the two loci are less than 4 Mb apart. Most of these patients also have psychomotor developmental delay, resulting from loss of another still undefined gene in the region.[117]

Clinical Features. Peripheral blood smears demonstrate only prominent spherocytosis (see Fig. 16-7, C). Hemolysis can be mild to severe, and the patients with recessive mutations typically have a more severe clinical course. Almost all dominant ankyrin mutations are private; that is, each individual kindred has a unique mutation. There is one exception, ankyrin$^{\text{Florianopolis}}$, a frameshift mutation that has been identified in HS patients from three unrelated kindreds.[118] Differences in a linked ankyrin gene polymorphism show that the three ankyrin$^{\text{Florianopolis}}$ alleles are different and arose independently.

Band 3 Defects: Dominant Hereditary Spherocytosis

Band 3 deficiency is present in approximately 25% to 45% of European and American patients with dominant HS,[57,119] and band 3 defects account for 37% of the known HS mutations.[87] Erythrocyte membranes from these patients are equally deficient in band 3 and protein 4.2,[120] which requires band 3 to bind to the red cell membrane. The characteristics of HS due to band 3 deficiency are listed in Table 16-7.

Defects in band 3 produce a variety of red cell phenotypes (Fig. 16-10), including stomatocytosis, cryohydrocytosis, Southeast Asian ovalocytosis (SAO), and acanthocytosis, as well as HS. These are discussed in later sections of the chapter. The HS mutations are spread throughout the band 3 gene, occurring in both the cytoplasmic and membrane-spanning domains. They include nonsense mutations, frameshift mutations, partial gene duplications, other missense mutations, and splicing defects. Many of the mutations cause messenger RNA (mRNA) instability or a misfolded protein that is degraded or not inserted into the membrane.[120] Conserved arginine residues are frequent sites of missense mutations in the transmembrane domain of the band 3 gene.[121,122] The affected arginine residues are all located in the same position on the inside edge of membrane-spanning segments and are believed to interact with negatively charged phospholipids in the inner bilayer and help orient the segments. As predicted, in vitro studies show that these arginine substitutions, as well as several other HS-associated band 3 missense mutations, exhibit defective cellular trafficking from the endoplasmic reticulum to the plasma membrane,[123,124] perhaps due to misfolding. Determination of the structure of the cytoplasmic domain of band 3[125,126] and detailed studies of the topography of the transmembrane domain[127,128] are beginning to provide insights into the biologic significance of the missense mutations.

Similar to the other molecular defects that cause HS, band 3 mutations are unique familial defects with no common mutations among affected groups.

Clinical Features. Clinically, most patients with band 3 mutations have mild to moderate hemolysis and anemia. The band 3 protein is reduced by 15% to 35% in HS red cells. On average, band 3 defects are somewhat milder than ankyrin or β-spectrin defects, although there is considerable overlap in severity. Patients with HS and

TABLE 16-7 Hereditary Spherocytosis Due to Band 3 Mutations

25%-45% of hereditary spherocytosis
Individual, dominant functionally null mutations. No common defects
15%-40% decrease in band 3 and a similar decrease in protein 4.2
Mild to moderate hemolysis and anemia
Spherocytosis with a small number of characteristic button mushroom-shaped or "pincered" cells in most patients

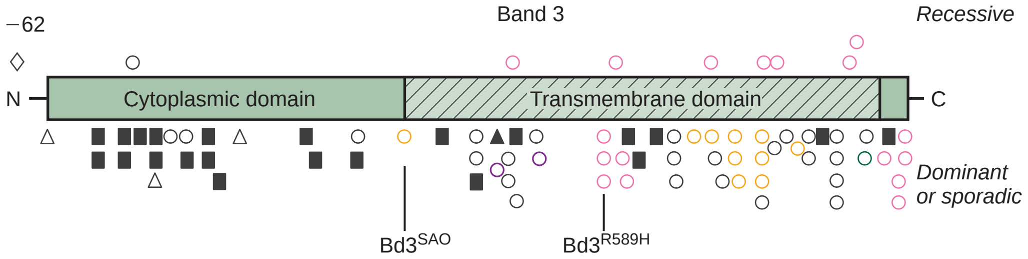

Figure 16-10 Band 3 mutations associated with hereditary spherocytosis (HS; *black*), various inherited disorders of cation permeability *(orange)*, distal renal tubular acidosis without *(pink)* or with *(purple)* hemolytic anemia, and hereditary acanthocytosis *(green)*. Missense mutations and in-frame insertions and deletions are indicated by *circles*. Nonsense and other null mutations are indicated by *squares*. Splicing mutations that abolish or nearly abolish band 3 expression are indicated by *solid triangles*. Splicing mutations that are or are presumed to be less severe are indicated by *open triangles*. One mutation in the 5′-untranslated region that is believed to decrease expression is indicated by a *diamond*. The cation permeability defects include stomatocytosis, cryohydrocytosis, a cryohydrocytosis-like form of HS, and Southeast Asian ovalocytosis. They are discussed later in the chapter.

band 3 deficiencies have a small number (≤1%) of button mushroom–shaped or "pincered" erythrocytes in addition to spherocytes on peripheral blood smears (see Fig. 16-7, *D*). This morphologic characteristic is not observed in the other membrane protein defects.

Distal Renal Tubular Acidosis. Distal renal tubular acidosis (dRTA) is a disorder characterized by the inability of the kidney to acidify the urine below pH 5.5 in the presence of systemic metabolic acidosis. It is caused by failure of H^+ secretion in the distal nephron. Patients present with various combinations of failure to thrive, hyperchloremic metabolic acidosis, hypokalemia, weakness, metabolic bone disease, and kidney stones. Because a shortened form of band 3 lacking the first 65 amino acids is expressed in the intercalated cells of the kidney cortical collecting ducts where its anion exchange capability is coupled to H^+ excretion, defects in band 3 would be expected to produce dRTA, and in fact a number of recessive and dominant missense mutations within the membrane domain of band 3 have been identified in dRTA patients (see Fig. 16-10).[129] The dominant defects tend to cluster in the middle of the membrane domain (Arg589His has been described in multiple kindreds) or at the C-terminus (see Fig. 16-10). The recessive mutations are localized throughout the membrane domain. The dominant mutations seem to be more prevalent in Europe, whereas the recessive mutations are more prevalent in Southeast Asia, but this may be because SAO (band 3^{SAO} or band $3^{\Delta 400\text{-}408}$) is very common in that part of the world (discussed later) and causes dRTA when it is coupled with a recessive dRTA allele.[129-131]

Surprisingly, few patients with HS due to band 3 defects have dRTA.[132-135] There are a few exceptions in patients who are homozygous or compound heterozygous for band 3 defects[28,136-139]; however, the majority of HS patients with mutations in band 3 do not have dRTA. Conversely, few patients with band 3 defects causing dRTA have hemolysis or spherocytosis.[132-133] In general, the dRTA mutations do not impair anion exchange.[132,133] They cause band 3 to either be retained in the endoplasmic reticulum or Golgi apparatus, or to be mistrafficked to the wrong membrane surface in polarized cells.[124,135,136,138-142] Most of the transport and trafficking studies have been done in oocytes, Madin-Darby canine kidney (MDCK) cells, or other epithelial cells and not in erythroid cell lines, so it is not possible to test whether band 3 trafficking is aberrant in kidney cells but not in red cells. This would explain why the dRTA mutants do not cause HS, and there is some evidence supporting the idea.[135] Another possibility is that dominant dRTA results from the association of mutant band 3 and wild-type band 3 into heterooligomers in the kidney, but not in erythroid cells, leading to intracellular retention or mistargeting of both proteins in the kidney and normal expression in red cells.[120]

Carbonic anhydrase II (CAII) binds to the C-terminus of band 3 and aids in chloride-bicarbonate transport.[135] Patients who lack CAII develop dRTA, osteopetrosis, and neurologic disease. This raises the possibility that some C-terminal band 3 dRTA mutations (see Fig. 16-10) may cause dRTA through loss of CAII function instead of, or in addition to, mistrafficking of band 3.

Protein 4.2 Defects: Recessive Hereditary Spherocytosis

HS caused by protein 4.2 deficiency is most common in Japan, although a few patients have been described in other populations. Overall, protein 4.2 mutations account for 9% of the published HS molecular defects.[87] The characteristics of this form of HS are summarized in Table 16-8.

Multiple protein 4.2 mutations have been described (Fig. 16-11). The most common one is 4.2^{Nippon}, in which the red cells contain only a small quantity of a 74/72-kD doublet of protein 4.2 instead of the usual abundant 72-kD species, because of an Ala142→Thr mutation that affects the processing of the protein 4.2 mRNA.[143] Protein 4.2^{Nippon}–deficient membranes lose 70% of their ankyrin with low ionic strength extraction, and the ankyrin loss is blocked by preincubation of the membranes with purified 4.2, which suggests that protein 4.2 stabilizes ankyrin on the membrane.[144,145] This hypothesis is supported by the observations that the amount of protein 4.2 is low in the red cell membranes of ankyrin-deficient *nb/nb* mice and in HS patients who lack one ankyrin gene. In addition, red cells from patients homozygous for 4.2^{Nippon} are fragile and have heat-sensitive skeletons, clumped intramembranous particles, and increased lateral mobility of

band 3.[145] A weakening of ankyrin–band 3 binding due to loss of protein 4.2 has also been observed.[146] However, ankyrin lability is not evident in all patients with protein 4.2 deficiency.[147,148] Patients whose red cells lack protein 4.2 also lack CD47.[149-151] CD47 connects the band3–ankyrin–4.2 complex to the Rh complex of which CD47 is a part. Loss of CD47 may also be important because CD47 is recognized by an inhibitory receptor on macrophages that blocks phagocytosis.[152]

Finally, partial erythrocyte protein 4.2 deficiency has also been associated with mutations of band 3.[43,153,154] Presumably, these mutations affect sites of band 3–protein 4.2 interactions.

Clinical Features. Clinically, patients with HS due to protein 4.2 deficiency have mild to moderate HS. The peripheral smear sometimes contains typical spherocytes, but it may also contain ovalocytes, stomatocytes, or spiculated cells and relatively few spherocytes (see Fig. 16-7, *E*). For this reason the diagnosis of HS may be missed in patients with protein 4.2 deficiency. The mechanism behind this unique and variable red cell morphologic picture is currently unknown.

Pathophysiology

Loss of Membrane Surface by Vesiculation

The primary membrane lesions in HS all involve vertical interactions between the skeleton and the bilayer and fit the theory that HS is caused by local disconnection of the skeleton from the bilayer and its integral membrane proteins, followed by vesiculation of the unsupported surface components. This, in turn, leads to progressive reduction in membrane surface area and to a shape called a spherocyte, although it usually ranges between a thickened discocyte and a spherostomatocyte.[155]

Biomechanical measurements show that HS membranes are fragile. The force required to fragment the membrane is diminished and is proportional to the density of spectrin on the membrane.[89,90] Membrane elasticity and bending stiffness are also reduced and are proportional to spectrin density.[156] In addition, HS red cells lose membrane more readily than normal red cells when metabolically deprived or when their ghosts are subjected to conditions facilitating vesiculation.[157,158] This has not been shown to occur in metabolically healthy HS spherocytes, perhaps because it occurs slowly (1% to 2% per day) under such conditions. However, massive vesiculation is evident in mice and zebrafish with severe spherocytic hemolytic anemias (Fig. 16-12).[159,160,161,162,163]

Because budding red cells are rarely observed in typical blood smears from patients with HS, the postulated vesiculation may either involve microscopic vesicles or occur in the reticuloendothelial system. Vesiculation may also occur in the bone marrow of patients with HS because similar decreases in the red cell surface area have been found in HS reticulocytes and in mature red blood cells.[164] When membrane vesicles are induced in normal red cells, they originate at the tips of spicules, where the lipid bilayer uncouples from the underlying skeleton (see Fig. 15-29).[165] The vesicles are small (≈100 nm) and devoid of hemoglobin and skeletal proteins and would be invisible by light microscopy. Tiny (50- to 80-nm) bumps have been detected by atomic force microscopy, on the surface of red cells obtained from patients with HS whose red cells are actively hemolyzing (Fig. 16-13).[166] The bumps could be microvesicles, although this needs to be proven. They are less than the length of a spectrin molecule (100 nm) and are not present on red cells from splenectomized patients.

Hypothesis 1. The observation that spectrin or spectrin/ankyrin deficiencies are common in HS has led to the suggestion that they are the primary cause of spherocytosis. According to this hypothesis (Fig. 16-14, hypothesis 1), interactions of spectrin with bilayer lipids or proteins are required to stabilize the membrane. Spectrin-deficient

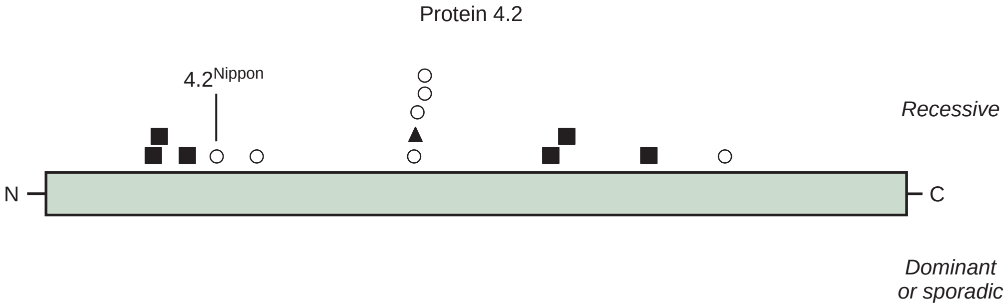

Figure 16-11 Protein 4.2 mutations associated with recessive hereditary spherocytosis (HS; *black*). Missense mutations and in-frame insertions and deletions are indicated by *circles*. Nonsense and other null mutations are indicated by *squares*. One splicing mutation that nearly abolishes protein 4.2 expression is indicated by a *solid triangle*. 4.2$^{\text{Nippon}}$ is a common mutation in Japanese cases.

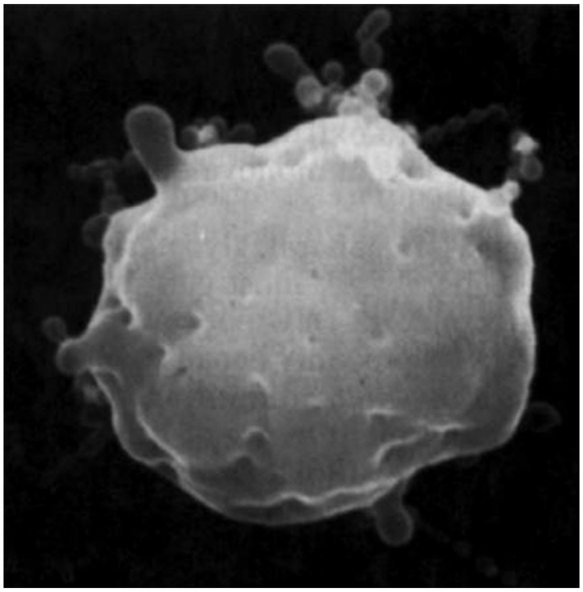

Figure 16-12 Scanning electron micrograph of a mouse red cell that lacks α-spectrin and has only trace amounts of β-spectrin. Note the extraordinary membrane instability and microvesiculation. It is assumed that similar vesiculation and membrane loss occur in human HS but at a much slower rate, consistent with the milder degree of spectrin deficiency in the human disease.

areas would tend to bud off, leading to spherocytosis. However, this conjecture does not explain how spherocytes develop in patients whose red cells are deficient in band 3 but have normal amounts of spectrin.

Hypothesis 2. An alternate hypothesis argues that the bilayer is stabilized by interactions between lipids and the abundant band 3 molecules (see Fig. 16-14, hypothesis 2). Each band 3 molecule contains about 12 hydrophobic transmembrane helices, many of which must interact with lipids. These interactions presumably spread beyond the first layer of lipids and influence the mobility of lipids in successive layers. In deficient red cells the area between band 3 molecules would increase, on average, and the stabilizing effect would diminish. Transient fluctuations in the local density of band 3 could aggravate this situation and allow unsupported lipids to be lost, resulting in spherocytosis. This hypothesis is supported by targeted disruption of the band 3 gene in mice. Erythrocytes from these mice lose massive amounts of membrane surface despite a normal membrane skeleton.[161] This concept is also consistent with early studies of intramembrane particle aggregation, which leads to particle-free domains, as discussed in Chapter 15. These domains are unstable, giving rise to surface blebs that are subsequently released from the cells as vesicles.[167]

It is most likely that both of these hypotheses operate to a different degree depending on the membrane skeletal protein which is deficient—hypothesis 1 dominating in spectrin and ankyrin disorders and perhaps in protein 4.2 deficiency, and hypothesis 2 dominating in band 3 defects. Hypothesis 1 predicts that released microvesicles will contain band 3 and other skeleton-linked integral membrane proteins; hypothesis 2 predicts such vesicles will contain mostly lipids. This should be testable but has not yet been examined.

Loss of Cellular Deformability

Hereditary spherocytes hemolyze because of the rheologic consequences of their decreased surface-to-volume ratio. The red cell membrane is very flexible, but it can only expand its surface area about 3% before rupturing.[168] Thus erythrocytes become less and less deformable as surface area is lost. Clever experiments show that the spleen begins to sense and restrain red cells that have lost as little as 2% to 3% of their membrane surface and that loss of more than 18% of the red cell surface leads to complete splenic sequestration.[169] This corresponds to the 15% to 20% loss of membrane lipids and, presumably, membrane surface in HS red cells.[157,170-172] For HS red

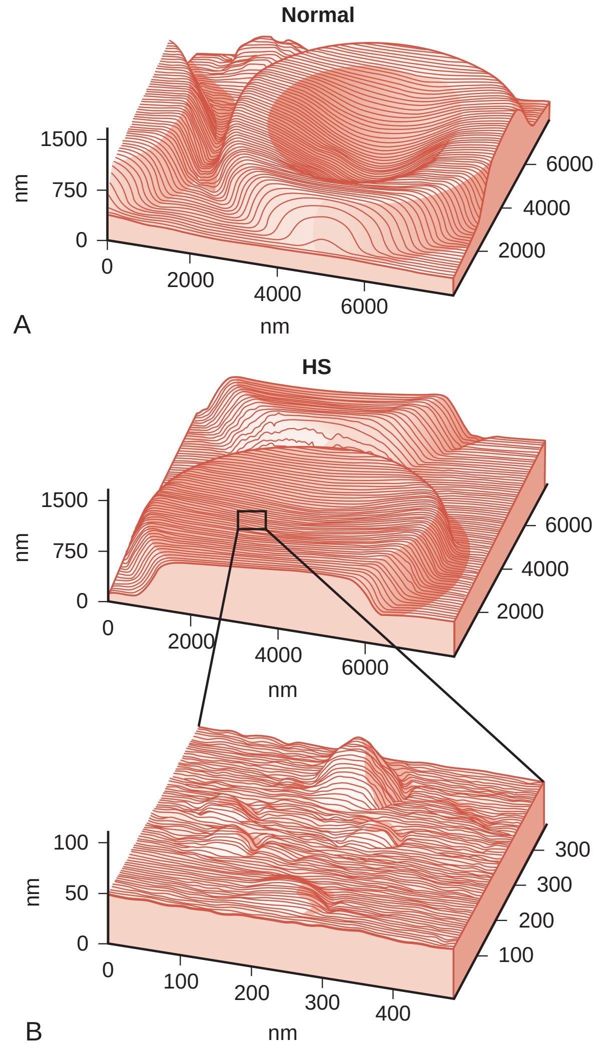

Figure 16-13 Comparison of the surface of a normal red cell (**A**) and a hereditary spherocyte (HS) (presplenectomy) (**B**) by atomic force microscopy. Note that at high magnification, 50 nanometers (nm) to 80 nm pseudopodia are evident on the surface of the spherocyte (bottom of **B**). These probably represent membrane microvesicles. They were not observed following splenectomy.

Figure 16-14 Pathophysiology of hereditary spherocytosis (HS). Hypothesis 1 assumes that the "membrane" (i.e., the lipid bilayer and the integral membrane proteins) is directly stabilized by interactions with spectrin or other elements of the membrane skeleton. Spectrin-deficient areas, lacking support, bud off, leading to spherocytosis. This may be the dominant mechanism in spectrin, ankyrin, and perhaps protein 4.2 deficiency. Hypothesis 2 assumes the membrane is stabilized by the interactions of band 3 with neighboring lipids. The influence of band 3 extends into the lipid milieu because the immobilized lipids adjacent to band 3 interact with and slow the lipids in the next layer, and so on. In band 3–deficient cells, the lipid area between band 3 molecules increases, and unsupported lipids are lost. This may be the primary mechanism in band 3 deficiency. Both mechanisms lead to loss of membrane surface, spherocytosis, reduced red cell deformability, and splenic trapping, where the unfavorable splenic environment shown in the box augments membrane loss, a process called splenic conditioning. Some red cells hemolyze, some escape as microspherocytes, susceptible to recapture, and some adapt by loss of cell volume (K^+ and H_2O), leading to a temporary reprieve before more membrane loss reinitiates the process. *(Modified from Perrotta S, Gallagher PG, Mohandas N: Hereditary spherocytosis.* Lancet *372:1411–1426, 2008.)*

cells, poor deformability is only a hindrance in the spleen, because the cells have a nearly normal life span after splenectomy.[173,174]

Splenic Sequestration and Conditioning

In the spleen most of the arterial blood empties directly into the splenic cords, a tortuous maze of interconnecting narrow passages formed by reticular cells and lined with phagocytes (see discussion of splenic structure and function in Chapter 23).[175-178,179,180] Histologically, this is an "open" circulation, but most of the blood that enters the cords normally travels by fairly direct (i.e., functionally closed) pathways. If passage through these channels is impeded, red cells are diverted deeper into the labyrinthine portions of the cords, where blood flow is slow and the cells may be detained for minutes to hours. Whichever route is taken, to reenter the circulation, red cells must squeeze through spaces between the endothelial cells that form the walls of the venous sinuses (Fig. 16-15). Even when maximally distended, these narrow slits are always much smaller than red cells, which are greatly distorted during their passage.[177,178] Experiments have shown that spherocytes are selectively sequestered at this cordal-sinus juncture.[181-185] As a consequence, spleens from patients with HS have massively congested cords and relatively empty sinuses.[175,182-184] In electron micrographs, few spherocytes are seen in transit through the sinus wall,[175,183,185] which contrasts to the situation in normal spleens, where cells in transit are readily found.[179]

During detention in the spleen, HS red cells undergo additional damage marked by further loss of surface area and an increase in cell density. Many of these "conditioned" red cells escape the hostile environment of the spleen and reenter the circulation. In unsplenectomized patients with HS, two populations of spherocytes are detectable: a minor population of hyperchromic "microspherocytes" that form the "tail" of very fragile cells in the unincubated osmotic fragility test and a major population that may be only slightly more spheroidal than normal.

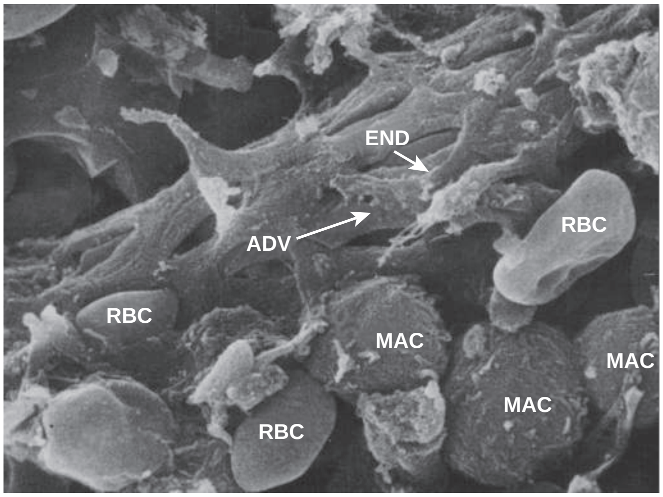

Figure 16-15 Scanning electron micrograph of a splenic sinus viewed from within the splenic cords. The narrow transmural slits between the endothelial cells *(END)* and adventitial cells *(ADV)* of the sinus are evident. The edges of these slits probably touch each other in the normal spleen, so the openings are potential structures rather than fixed pores. They are revealed here because of a drying artifact. Note that the adjacent erythrocytes *(RBC)* are considerably larger than the slits and hence must be flexible to pass into the splenic sinuses and return to the venous circulation. If they are unable to pass into the sinuses, macrophages *(MAC)* lie in wait. *(From Weiss L: A scanning electron microscopic study of the spleen.* Blood *43:665–691, 1974.)*

By 1913, it was known that HS red cells obtained from the splenic vein were more osmotically fragile than those in the peripheral circulation.[186] However, the significance of this finding was not clear until the classic studies in the 1950s by Emerson and Young, who showed that osmotically fragile microspherocytes are concentrated in and emanate from the splenic pulp (Fig. 16-16).[181,187] After splenectomy, spherocytosis persists, but the tail of hyperfragile red cells is no longer evident on osmotic fragility testing. These and other data led to the conclusion that the spleen detains and "conditions" circulating HS red cells in a way that increases their spheroidicity and hastens their demise.[181,187-189] The kinetics of this process were beautifully illustrated in vivo by Griggs, who found that a cohort of ^{59}Fe-labeled HS red cells gradually shifted from the major, less fragile population to the more fragile, conditioned population 7 to 11 days after entering the circulation.[189] Although most conditioned HS red cells that escape the spleen are probably recaptured and destroyed, the damage incurred is sufficient to permit extrasplenic recognition and removal, because conditioned spherocytes, isolated from the spleen and reinfused postoperatively, are rapidly eliminated.[189,190]

The mechanism of splenic conditioning is less certain. It is difficult to obtain accurate information about the cordal environment, but the existing data suggest it is metabolically inhospitable. Crowded red cells must compete for limited supplies of glucose[191] in acidic surroundings (pH 6.8 to 7.2)[192,193] where glycolysis is inhibited.[194,195] The acidic environment induces Cl^- and water entry and cell swelling[196] but also stimulates the K^+,Cl^- cotransporter, which produces a net loss of K^+ and water from the cells. The adverse effects of the cordal environment are further compounded by the presence of oxidant-producing macrophages. It has also been suggested that methylation of erythrocyte membrane proteins could contribute to the splenic conditioning of spectrin-deficient HS red cells.[197] Hence, the spherocyte, detained in the splenic cords because of its surface deficiency, is stressed by erythrostasis in a metabolically threatening environment.

Erythrostasis

The spherocyte is particularly vulnerable to erythrostasis. This is the basis of the well-known autohemolysis test.[198] During prolonged sterile incubation in the absence of supplemental glucose, red cells undergo a series of changes that culminate in hemolysis. The sequence of the changes is the same for HS and normal red cells; however, because HS cells are abnormally leaky and bear unstable membranes, their degeneration is accelerated.

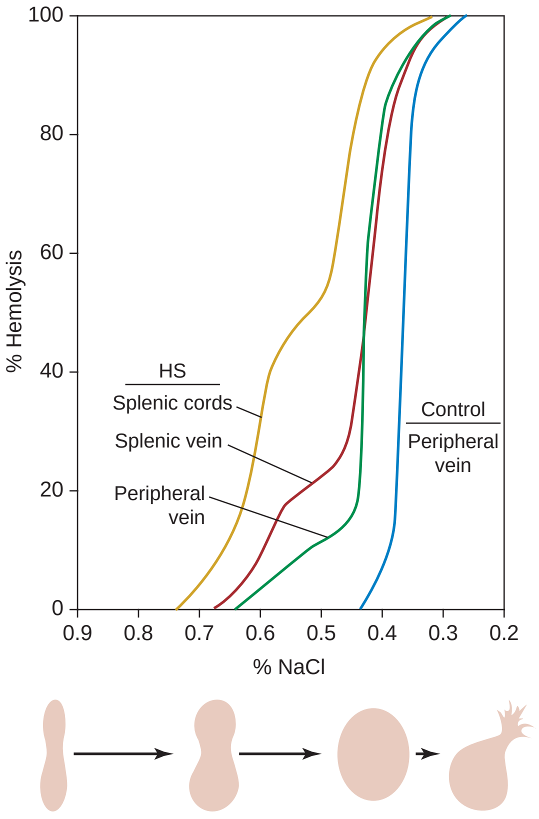

Figure 16-16 Osmotic fragility in hereditary spherocytosis *(HS)*. In the osmotic fragility test, red cells are suspended in salt solutions of varying tonicities between isotonic saline (0.9% NaCl) *(left)* and distilled water *(right)*. Normal red cells swell in hypotonic media and eventually reach a limiting spherical shape, beyond which they hemolyze *(bottom)*. Spherocytes, which begin with a lower than normal surface-to-volume ratio, can swell less before they reach their limiting volume; hence, their osmotic fragility curve is shifted to the left (higher salt concentrations). They are said to be osmotically fragile. Before splenectomy, a small proportion of the red cells are extra fragile "microspherocytes" and produce a "tail" on the osmotic fragility curve. The cells have been conditioned by the spleen, as shown by their higher concentration in the splenic vein and especially the splenic cords.

HS red cells are initially jeopardized, because their membrane permeability to Na^+ is mildly increased.[199] Their propensity to accumulate Na^+ and water is normally balanced by increased Na^+ pumping; however, the increased dependence on glycolysis is detrimental in erythrostasis, where substrate is limited.[199] HS red cells exhaust serum glucose and become ATP depleted more rapidly than normal red cells. As ATP levels fall, ATP-dependent Na^+,K^+ and Ca^{2+} pumps fail, and the cells gain Na^+ and water and swell. Later, when the Ca^{2+}-dependent K^+ (Gárdos) pathway is activated, K^+ loss predominates and the cells lose water and shrink. The Na^+ gain is accelerated in HS red cells but is insufficient by itself to induce hemolysis. However, HS red cells are doubly jeopardized. As noted earlier, they are inherently unstable and fragment excessively during metabolic depletion.[157,158,200] Membrane lipids (and probably integral membrane proteins) are lost at more than twice the normal rate.[158] At first this surface loss is balanced by cell dehydration, but eventually (within 30 to 48 hours) membrane loss predominates, the cells exceed their critical hemolytic volume, and autohemolysis ensues.

Consequences of Splenic Trapping

Calculations indicate that the average normal red cell passes through the splenic cords about 14,000 times during its lifetime and has an average transit time of 30 to 40 seconds,[201] surprisingly close to measured transient times in normal human spleens in vivo.[202] The calculated residence time of the average HS red cell in the splenic cords is much longer, perhaps as long as 15 to 150 minutes, but still far short of the time required for metabolic depletion to occur.[201] This conclusion is supported by direct analysis of splenic red cells. HS red cells obtained from the splenic pulp and containing 80% to 100% conditioned cells are moderately cation depleted and show changes in adenosine diphosphate (ADP) and 2,3-DPG concentrations consistent with metabolism in an acidic environment, but their ATP levels are normal.[203] Others have reported similar results.[204,205]

The data suggest that splenic conditioning is caused by mechanisms other than ATP depletion. For example, K^+ loss and membrane instability may be exacerbated by the high concentrations of acids and oxidants that must exist in a spleen filled with activated macrophages lunching on trapped HS red cells. In vitro, oxidants from activated phagocytes can diffuse across the membranes of bystander red cells and damage intracellular proteins within minutes. Red cells moving through the rapid transit pathways in the spleen might escape damage, but those caught in cordal traffic would be vulnerable. Oxidants, even in relatively low concentrations, cause selective K^+ loss by a variety of mechanisms[206,207] and also damage membrane skeletal proteins.[208,209] Finally, there is some evidence that HS red cells may be abnormally sensitive to oxidants.[209,210] When exposed to peroxides they undergo remarkable blebbing and, presumably, vesiculation. If a similar process occurs in the spleen, it could be responsible for the excessive surface loss observed in conditioned cells.

The possibility that macrophages may directly condition HS red cells should also be considered. It is well known that spherocytosis often results from the interaction of immunoglobulin G (IgG)–coated red cells with macrophages, but HS red cells do not have abnormal levels of surface IgG.[211] Macrophages also bear receptors for oxidized lipids (scavenger receptor) and phosphatidylserine, but there is no evidence at present that HS red cells expose the relevant ligands. The involvement of macrophages is supported by observations that large doses of corticosteroids markedly ameliorate HS in unsplenectomized patients.[212-214] The effects are similar to those produced by splenectomy. It is well known that similar doses of corticosteroids inhibit splenic processing and destruction of IgG- or C3b-coated red cells in patients with immunohemolytic anemias, probably by suppressing macrophage-induced red cell sphering and phagocytosis.[215,216] Electron microscopy shows that splenic erythrophagocytosis is common in HS, particularly in the splenic cords.[183,185,217] In addition, phagocytes expressed from the cords of patients with HS contain bits of ghost-like "debris,"[218] presumably resulting from membrane fragmentation.

Adaption: Benefits of Red Cell Dehydration for the HS Red Cell

It has been known for many years that HS red cells intrinsically leak more Na^+ and K^+ ions than normal cells.[199,219] All the Na^+ transmembrane movements are increased, including passive diffusion, Na^+,K^+-ATPase pump, Na^+,K^+,$2Cl^-$ cotransport, and Na^+, Li^+ countertransport.[220] The excessive Na^+ influx activates the Na^+,K^+-ATPase pump, and the accelerated pumping, in turn, increases ATP turnover and glycolysis. At one time, it was believed that this modest Na^+ leak was responsible for the hemolysis of hereditary spherocytes,[199] particularly those cells trapped in the unfavorable metabolic environment of the spleen, but it now is clear that this is incorrect, because the magnitude of the Na^+ flux does not correlate with the extent of hemolysis in HS.[220,221]

The dehydration of HS red cells, as reflected in their high MCHC, is likely to be caused, at least in part, by the adverse environment of the spleen. This assumption has been made on finding that spherocytes from surgically removed spleens are the most dehydrated.[203] The pathways causing HS red cell dehydration have not been clearly defined. One likely candidate is the Gárdos channel, a Ca^{2+}-activated K^+ channel, which is known to contribute to erythrocyte dehydration in sickle cell anemia and thalassemia. One study showed that the Gárdos channel is functionally upregulated in a form of mouse HS caused by lack of erythrocyte protein 4.1R.[222] When these mice were treated with clotrimazole, a known Gárdos channel blocker, hemolysis and anemia worsened, indicating that red cell dehydration protected the hereditary spherocytes, presumably by preserving their surface-to-volume ratio and therefore their flexibility in the face of surface loss.[222]

Another possible cause of red cell dehydration in HS is increased K^+,Cl^- cotransport, which is activated by acid pH.[223] HS red cells, particularly from unsplenectomized subjects, have a low intracellular pH,[54] reflecting the low pH of the splenic environment. The K^+,Cl^- cotransport pathway is also activated by oxidation,[224] which is likely to be caused by splenic macrophages.

Hyperactivity of the Na^+,K^+ pump, triggered by increased intracellular Na^+, can dehydrate red cells directly, because three Na^+ ions are extruded in exchange for only two K^+ ions. The loss of monovalent cations is accompanied by water.

A fourth possible cause is the recently described mechanosensitive Piezo1 channel, which responds to membrane stretch and is thought to be involved in homeostatic adjustments to changes in volume.[225,226] It is defective in hereditary xerocytosis,[227,228,229] a disease characterized by red cell dehydration.

Whichever transport pathways cause HS red cells to lose K^+ and water, it is likely that the dehydration is a form of "adaption" (Fig. 16-14) that prolongs the life of the HS red cell. How much it does so is unknown. Polymorphisms in cation channels like Piezo1 and calcium ATPase 4, in the globin loci, in major membrane skeletal proteins, and in genes like *TAF3*, *DNAJA4*, *WDR61* and *HBS1L-MYB* are associated with variation in human MCHC.[230-231b] It will be interesting to see if these genes affect the severity of HS.

Laboratory Characteristics

Most of the classic laboratory features of HS are those found in other forms of hemolytic anemia, such as reticulocytosis, erythroid hyperplasia of the bone marrow, indirect hyperbilirubinemia, and increased fecal urobilinogens.[35,36,232] The plasma hemoglobin level is often normal,[233] and the haptoglobin value is only variably reduced,[234] because most of the hemoglobin that is released when HS red cells are destroyed is catabolized at the site of destruction, so-called extravascular hemolysis. The spherocytic morphology combined with laboratory tests that measure a loss of surface area, such as the osmotic fragility test or eosin-5′-maleimide–binding test, distinguish HS from most other forms of hemolytic anemia. Membrane protein analysis and molecular genetic testing are only performed in research laboratories, as these tests are expensive and not very useful clinically. This is likely to change in the near future, though, as the cost of whole-exome and even whole-genome sequencing is falling very rapidly.

Red Cell Morphology

Spherocytes (see Fig. 16-2) are the hallmark of HS. They are dense, round, and hyperchromic; lack central pallor; and have a decreased mean cell diameter. They are always evident in blood smears from patients with moderate or moderately severe HS but are obvious in only 25% to 35% of patients with mild HS.[22,35,36] Hereditary spherocytes are technically misnamed, as they range in shape from thickened discocytes to spherostomatocytes when examined under the scanning electron microscope.[155]

In patients with HS, spherocytes and microspherocytes are the predominant abnormal cells on the peripheral blood smear (other than polychromatophils). However, there are morphologic variations that occur with some of the specific membrane defects in HS (see Fig. 16-7). Patients with ankyrin defects, the most common subgroup, have typical smears (see Fig. 16-7, *C*),[57] but many patients with β-spectrin defects also have a subpopulation of acanthocytes or hyperchromic echinocytes (see Fig. 16-7, *B*)[97,98] and most patients with band 3–deficient HS also have a small number of button mushroom–shaped red cells on their smears (see Fig. 16-7, *D*).[235] In severe HS, caused by homozygous or compound heterozygous α-spectrin mutations or by severe ankyrin defects, misshapen spherocytes, spiculated red cells, and bizarre poikilocytes may be seen and even dominate the blood smear (see Fig. 16-7, *A*). Red cell morphologic findings are variable in protein 4.2 deficiency. Some patients have typical spherocytosis,[144] but acanthocytes, echinocytes, ovalostomatocytes, and other poikilocytes have been observed in others[236] (see Fig. 16-7, *E*). Finally, some patients with truncated β-spectrin chains have spherocytic elliptocytosis (see later).

In contrast to red cells in IgG-mediated autoimmune hemolytic anemias, where spherocytosis also dominates the blood picture, HS red cells lose most of their surface area in the bone marrow instead of in the circulation.[164] Nucleated red cells are uncommon in blood smears,[35] except in the most severe forms of HS.[60] Howell-Jolly bodies are also uncommon before splenectomy (4% of patients)[35] and suggest reticuloendothelial blockade.

Red Cell Indices

Most patients have mild to moderate HS with mild anemia (hemoglobin level of 9 to 12 g/dL) or no anemia at all (so-called compensated hemolysis). In moderate to severe HS, the hemoglobin concentration ranges from 6 to 9 g/dL. In patients with the most severe disease, the hemoglobin concentration may drop to as low as 4 to 5 g/dL. The reticulocyte count is elevated without a comparable increase in the immature reticulocyte fraction.

The MCHC of HS red cells is increased due to relative cellular dehydration.[36] The average MCHC exceeds the upper limit of normal (36%) in about one half of patients with HS, but all patients have some dehydrated cells.[36] The Technicon H1 blood counter and its successors, which use the principle of flow cytometry (i.e., dual-angle laser light scattering), measure the mean corpuscular volume (MCV) and MCHC directly and provide histograms of both parameters. There is a right shift of the MCHC histogram in HS with an increased (>4%) population of hyperdense cells (MCHC > 41 g/dL) due to red cell dehydration, and a broadening of the distribution of MCVs, due to the mixture of microspherocytes and reticulocytes (Fig. 16-17). This excess proportion of hyperdense cells is accurate enough to identify nearly all patients with HS[237-240] and is one of the easiest and most accurate ways to diagnose the disease when one member of a family is already known to have HS.

The MCV usually falls within the lower normal range in HS,[24,33,36] but it is low in about 8% of adults and 16% of children, especially those with more severe HS.[24,33] It is rare for the MCV to be less than 70 fL unless there is concomitant thalassemia or iron deficiency. However, the MCV is low relative to the age of the cells (reticulocytes

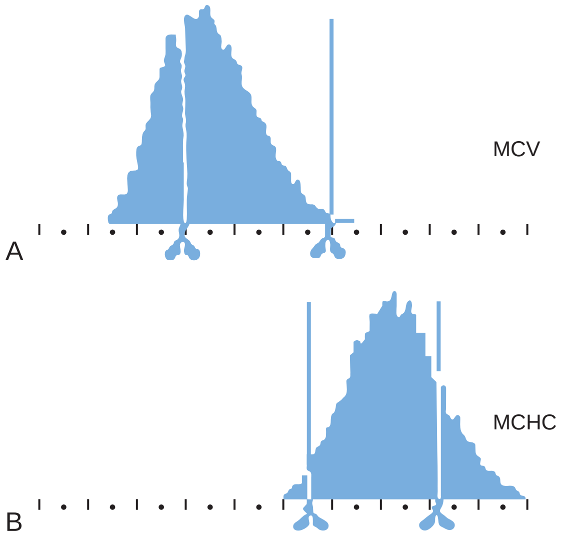

Figure 16-17 Histogram of the distribution of mean cell volume *(MCV)* (**A**) and mean cell hemoglobin concentration *(MCHC)* (**B**) in red cells of a patient with hereditary spherocytosis (HS) before splenectomy. The vertical lines mark the normal limits of the distributions. For the volume distribution, they separate microcytic cells (<60 fL) and macrocytic cells (>120 fL) from normocytic red cells (60 to 120 fL). For the hemoglobin concentration distribution, they separate hypochromic cells (<28 g/dL) and hyperdense cells (>41 g/dL) from normochromic cells (28 to 41 g/dL). The data were collected with a laser-scattering blood counter. Note that the HS patient has subpopulations of microcytes (low MCV) and dehydrated cells (high MCHC). All 21 HS patients in this study had similar subpopulations. *(Modified from Pati AR, Patton WN, Harris RI: The use of the Technicon H1 in the diagnosis of hereditary spherocytosis.* Clin Lab Haematol *11:27–30, 1989.)*

have a high MCV) in all patients with HS, reflecting the dehydrated state of HS red cells. The reticulocyte MCV is also low, which contrasts with IgG-mediated autoimmune hemolytic anemia, where spherocytes are present but the reticulocyte indices are normal.

The RDW of HS erythrocytes is also very high, particularly in patients with more severe disease (see Table 16-3).[33]

Various studies show that the MCHC or the percentage of hyperdense cells and the high RDW discriminate HS patients from normal individuals,[240-242] though less so following splenectomy.[243] An MCHC greater than 35 g/dL has a sensitivity of 70% and a specificity of 86% in diagnosing HS; an RDW greater than 14 has 85% sensitivity and 97% specificity.[241] Combining the MCHC with the erythrocyte distribution width leads to a specificity approaching 100%.[240] The RDW, MCHC, hemoglobin : MCHC ratio, and hemoglobin : RDW ratio all correlate with the severity of disease (see Table 16-3).[33,238]

Fragility and Autohemolysis Tests

Osmotic Fragility Test. Osmotic fragility testing (see Fig. 16-16) is performed by suspending red cells in increasingly hypotonic buffered NaCl.[188,244,245] In hypotonic solutions, normal erythrocytes increase their volume by swelling until they become spherical and burst, releasing hemoglobin into the supernatant. Cells that begin with a decreased surface-to-volume ratio, like spherocytes or stomatocytes, reach the spherical limit at a higher NaCl concentration than normal cells and are termed osmotically fragile. Freshly drawn red cells from approximately one fourth of individuals with HS will have a normal or nearly normal osmotic fragility curve, approximating the number of HS patients with few spherocytes seen on their peripheral blood smears.[37,246] However, after incubation at 37°C for 24 hours, HS red cells lose membrane surface area more readily than normal red cells, because their membranes are leaky and unstable. This incubation accentuates the defect in HS erythrocytes and brings out the defect of osmotic fragility. When the spleen is present, a subpopulation of very fragile erythrocytes that have been conditioned by the spleen form the "tail" of the osmotic fragility curve. This tail disappears after splenectomy.

The osmotic fragility test detects as abnormal (i.e., osmotically sensitive) any red cells with a decreased surface-to-volume ratio. This includes red cells in hereditary stomatocytosis (HSt), hereditary pyropoikilocytosis (HPP), autoimmune hemolytic anemia, and, sometimes, congenital dyserythropoietic anemia, type II (CDAII). Red cells with a large surface-to-volume ratio, whether owing to an increase in membrane surface, like target cells, or to cellular dehydration, like hereditary xerocytes, have decreased osmotic fragility (i.e., are osmotically resistant).

The incubated osmotic fragility test is thought to be more sensitive than the unincubated osmotic fragility test, although this is not well proven. For a long time the osmotic fragility test, particularly the incubated test, was the gold standard test for diagnosing HS,[246] but recent comparisons[24,247,248] show that other tests are more sensitive and specific.

Acidified Glycerol Lysis Test and Pink Test. The glycerol lysis test was developed as an alternative to the osmotic fragility test and is widely used in Europe. In this test, red cells are incubated in glycerol-sodium phosphate–buffered hypotonic saline solution. The glycerol slows the entry of water into the cells, so that the time for the cells to lyse is prolonged and can be measured accurately. The glycerol lysis time is shortened for HS red cells because of the reduced surface-to-volume ratio.

The original glycerol lysis test lacked sensitivity and specificity,[24,247] but the acidified glycerol lysis test (AGLT),[24,247,249] and especially its incubated variant,[250-252] have a high sensitivity (82% to 98%) and specificity (91% to 95%). Another variation achieves 100% sensitivity and specificity by changing the concentration of the sodium phosphate buffer from 5.3 to 9.3 mmol/L.[18] This eliminates the need for preincubation. The modified test is easy to perform and requires very little blood, though accurate control of pH is critical. The simplicity of this test allows it to be used for rapid screening of a large number of blood samples.

Another adaptation of the original glycerol lysis test is the Pink test.[253] Modifications of the test have made it adaptable to microsize samples (e.g., fingerstick blood samples).[254,255] However, direct comparisons suggest that it is less specific than the osmotic fragility test or incubated AGLT.[250]

The AGLT, like the osmotic fragility test, is often abnormal in patients with autoimmune hemolytic anemia, but it is also sometimes abnormal in a variety of other conditions, including CDAII, paroxysmal nocturnal hemoglobinuria, hereditary elliptocytosis, myelodysplastic syndromes, mechanical hemolysis, and chronic renal failure, and in pregnancy.[247,249-252]

Hypertonic Cryohemolysis Test. This method is based on the fact that HS red cells are particularly sensitive to cooling at 0°C in hypertonic solutions, which causes the cells to lyse and release hemoglobin.[256,257] The molecular basis for this sensitivity is not understood, which is a disadvantage, but the test is reported to have a high sensitivity (90% to 100%)[256-258] with one exception (79%),[248] and to have good specificity (94% to 100%).[248,256-258] It is very easy to perform, requires very little blood (a capillary blood sample is sufficient[256,259]), and is compatible with the common blood specimens anticoagulated with ethylenediaminetetraacetic acid (EDTA). These qualities make it a good test for large-scale screening. The hypertonic cryohemolysis test is not widely used but deserves more attention.

Autohemolysis Test. The autohemolysis of erythrocytes after 48 hours at 37°C is normally less than 5% in the absence of glucose or less than 1% in the presence of glucose. Autohemolysis of spherocytes increases to 15% to 45% in the absence of glucose.[37,198,260] In HS, the degree of autohemolysis is reduced by the addition of glucose,[37,260,261] whereas in red cell glycolytic disorders and acquired disorders such as immune-mediated anemias, the degree of autohemolysis is not reduced. Although this differentiation may be occasionally helpful, the autohemolysis test is time consuming and cumbersome; gives variable results, with a sensitivity of only 70% to 80% and a specificity of 80% to 90%[248]; and is rarely performed.

Eosin-5′-Maleimide–Binding Test

When red blood cells are treated with the fluorescent probe eosin-5′-maleimide (EMA), 80% of the fluorophore binds to Lys430 on the outside surface of band 3. The other 20% binds to three proteins in the Rh complex: the Rh blood group proteins, RhAG, and CD47.[262] Thus the measurement of EMA fluorescence detects loss of membrane surface if that loss includes band 3 or the Rh complex. The EMA test is usually done with a flow cytometer so the fluorescence of individual cells is quantified.[263] Because membrane vesicles containing band 3 are believed to be lost in HS due to spectrin and ankyrin deficiency (see Fig. 16-14) and CD47 and, perhaps, band 3 molecules are lost in HS due to protein 4.2 deficiency,[149-151] the EMA test detects all the different forms of HS, not just HS due to primary band 3 deficiency. The test is both highly sensitive (92% to 100%) and highly specific (94% to 100%) for HS.[247,263-267] The only exception is one study that reported only 70% specificity.[248] The test requires very little blood, does not require preincubation, takes little time to perform, is not affected by storage of red cells for a week,[247] and is probably the single best test for diagnosing HS at the present time. It is recommended by the General Haematology Task Force of the British Committee for Standards in Haematology,[14,267a] and when combined with the AGLT achieved 100% sensitivity in one recent comparison of tests for HS.[247] In particular, the test is normal in autoimmune hemolytic anemias, which give false-positive results in the osmotic fragility test, AGLT, and cryohemolysis test. The EMA test is abnormal in disorders where membrane surface is decreased or band 3 is abnormal, such as HPP, SAO, cryohydrocytosis, congenital dyserythropoietic anemia, type II, and $\mathrm{Rh}_{\mathrm{null}}$ disease. However, these are all rare disorders and are fairly easy to distinguish by red cell morphologic findings and other criteria.

Osmotic Gradient Ektacytometry

The ektacytometer is a laser diffraction viscometer, a device that measures how much red cells are deformed by shear stress. The device can be used to measure membrane mechanical strength by determining the shear stress needed to fragment isolated red cell membranes,[268,269] or it can be used to assess red cell surface area, surface-to-volume ratio, and cellular hydration by measuring red cell deformation as a function of osmolarity at a constant shear stress.[270,271] The latter method is termed osmotic gradient ektacytometry and is the gold standard method for diagnosing HS (Fig. 16-18). One study demonstrated a 100% detection rate of HS using osmotic gradient ektacytometry and only a 66% detection rate of HS using the osmotic fragility test in the same population.[271] Unfortunately, only a few laboratories in the world are equipped with an ektacytometer and the instrument is no longer commercially available.

Membrane Protein, RNA, and DNA Measurements

Specialized tests are occasionally used to study patients with complicated disease or those for whom additional information is desired. Useful tests for these purposes include structural and functional studies of erythrocyte membrane proteins, such as protein quantitation, limited tryptic digestion of spectrin, membrane protein synthesis and assembly, and ion transport studies.

Membrane protein concentrations are usually assessed using SDS gels. Individual stained bands are quantified by densitometry or by eluting the dye from an excised band and measuring its concentration spectrophotometrically. This technique is satisfactory for detecting spectrin deficiency (expressed as a spectrin-to–band 3 ratio),[32] although it is not as accurate as a radioimmunoassay[100] or enzyme-linked immunoassay.[32] With densitometry, spectrin and ankyrin deficiencies may be underestimated because they are normalized to band 3, which is partially lost along with membrane lipids as spherocytes circulate. As a result, the spectrin-to–band 3 ratio is lower after splenectomy. This is even more true for ankyrin, which is present in smaller amounts, migrates close to β-spectrin on SDS gels, and is elevated in reticulocytes.[272] It is likely that patients with ankyrin defects, who have combined spectrin and ankyrin deficiency, are often misdiagnosed as having pure spectrin deficiency on SDS gels. SDS gels are satisfactory for detecting band 3

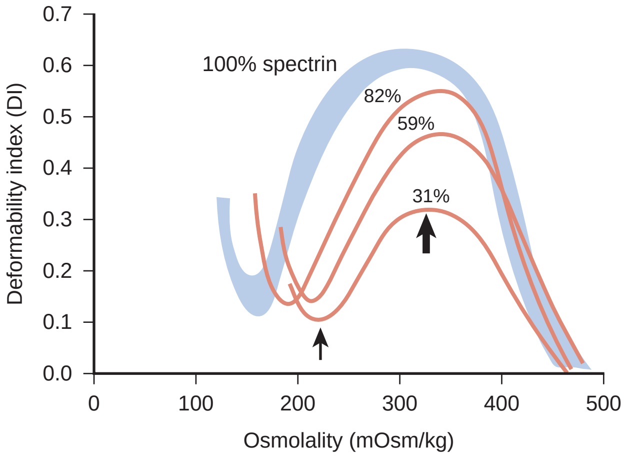

Figure 16-18 Osmotic gradient ektacytometry of hereditary spherocytosis (HS) erythrocytes with differing degrees of spectrin deficiency. In this technique, red cells are stretched by flow in a viscometer in a solution of gradually increasing osmolarity and the degree of red cell deformation is measured by laser diffraction. The deformability index *(DI)*, an arbitrary measure of deformation, is plotted as a function of the osmolarity. In the HS red cells *(red-brown lines)*, the minimum DI observed in the hypotonic region *(thin arrow)* is shifted to the right of the control region *(blue shaded area)*, indicating a decrease in the cell surface area–to-volume ratio. The maximum DI (DI_{max}) associated with the spectrin-deficient HS red cells *(thick arrow)* is less than that of control cells due to the reduced surface area of the HS cells. The more pronounced the spectrin deficiency, the greater is the loss of surface area and the lower is the DI_{max}. The osmolality in the hyperosmolar region at which the DI reaches half of its maximum value is a measure of the hydration state of the red cells. It is decreased in the HS patient with the lowest spectrin content, indicating cellular dehydration. *(Modified from Tse WT, Lux SE: Hereditary spherocytosis and hereditary elliptocytosis. In Scriver CR, Beaudet AL, Sly WS, Valle D, editors:* The metabolic and molecular bases of inherited disease, *8th ed. New York, 2001, McGraw-Hill p. 4665–4727.)*

deficiency (elevated spectrin-to–band 3 ratio) or protein 4.2 deficiency, and they are useful in combination with antibody staining (Western blots) for detecting mutant proteins of altered size.

Moreover, SDS gels do not always identify the abnormal protein in HS, because missense mutations may cause functional defects rather than quantitative defects and because protein deficiencies may be as small as 10%. Therefore several other approaches have been described in an attempt to define specific molecular defects. In families with multiple affected members, linkage analysis has been performed to include or exclude the candidate genes. In addition, suspected proteins can be sequenced using direct nucleotide sequence analysis of polymerase chain reaction (PCR)–amplified complementary DNA (cDNA) or genomic DNA. Currently, no commercial laboratories identify the molecular defects in HS membrane proteins, and these analyses are performed only by a few research laboratories. However, with the rapidly falling costs of both whole-exome and whole-genome sequencing it is likely that DNA sequencing may become the most cost-effective way to diagnose HS (and many other inherited diseases) in the near future. Because HS membrane protein mutations are mostly restricted to specific families and do not predict the severity of the disease, in most cases it is not clinically important to know the exact molecular defect. More detailed studies, sometimes including DNA sequencing, should be considered in patients where the diagnosis is unclear after standard testing and in patients whose HS is more severe than in other family members, possibly due to coinheritance of another deleterious allele.

Differential Diagnosis

In general, HS is easily diagnosed if there are typical laboratory findings of spherocytosis, Coombs negative hemolysis, increased osmotic fragility, high MCHC, high RDW, and a positive family history. However, HS must be differentiated from other causes of spherocytosis, and there are several situations in which diagnosis can be difficult. Other causes of spherocytosis are listed in Table 16-1.

ABO Incompatibility in Neonates

In the neonatal period it may be challenging to differentiate HS from ABO incompatibility.[273] Anemia, hyperbilirubinemia, circulating microspherocytes, and altered osmotic fragility are found in both conditions, and results of the direct Coombs test are sometimes negative in ABO incompatibility. However, in most infants with ABO incompatibility and significant hemolysis, anti-A (or anti-B) antibodies can be eluted from the red cells, and free anti-A (or anti-B) IgG antibodies can be detected in the infant's serum. The combination of HS and ABO incompatibility, though rare, is particularly severe.[274]

Immunohemolytic Anemias

Occasionally, patients with immunohemolytic anemias and spherocytosis also have so few antibody molecules attached to their red cells that results of the direct Coombs test are negative. In these rare cases, the differentiation of the disease from HS is possible only with the use of radioactive antiglobulin reagents, the so-called super–Coombs test.[275]

Heinz Body Hemolytic Anemias

Spherocytosis is also seen in Heinz body hemolytic anemias during an acute hemolytic crisis and occasionally in the steady state. However, in this situation, bite cells and/or blister cells and various dense, irregular cells are always present on the peripheral blood smear, and Heinz bodies can often be detected in red cells supravitally stained with methyl violet.

Aplastic Crises

Diagnostic difficulties may also arise in HS patients who are seen during an aplastic crisis (see below). Early in the crisis, the acute nature of the symptoms may suggest an acquired process and the absence of reticulocytes may divert the physician from a diagnosis of hemolytic anemia. Later, as marrow function returns, physicians may occasionally be misled by the properties of the emerging young HS red cells, which are less spherocytic and osmotically fragile than usual.

Congenital Dyserythropoietic Anemia, Type II

In a preliminary report, Mariani et al[276] noted that 13% of cases referred to their reference laboratory with a provisional diagnosis of HS were found to have CDAII, a disorder featuring underglycosylated band 3 and prominent binuclearity of late erythroblasts that is caused by defects in the secretory pathway gene *SEC23B* (see Chapter 7). Although CDAII patients typically display a variety of morphologic findings, a subset have prominent spherocytosis or elliptocytosis.

Hereditary Stomatocytosis and Xerocytosis

As discussed later in this chapter, patients with disorders of cation permeability, especially hereditary stomatocytosis (HSt) and hereditary xerocytosis (HX), may be misdiagnosed as having HS because they have a dominant hemolytic anemia with an abnormal osmotic fragility test. Care must be taken to exclude these disorders in any HS patient who is to be treated with splenectomy because there is a high risk of thromboembolic complications following splenectomy in patients with HSt and HX.[277]

Conditions That Camouflage Hereditary Spherocytosis

HS may be camouflaged by disorders that increase the surface-to-volume ratio of the red cells, such as iron deficiency,[278] vitamin B_{12} or folate deficiency,[279] obstructive jaundice,[170] β-thalassemia,[280] or sickle cell–hemoglobin C disease (hemoglobin SC disease).[281] In these difficult cases, additional tools, such as red cell membrane protein analysis, or exome or genome sequencing may be necessary to confirm the diagnosis of HS.

Iron Deficiency

Iron deficiency corrects the abnormal shape, fragility, and high MCHC of hereditary spherocytes but does not improve their life span.[278] Megaloblastic anemia can mask the morphologic characteristics of HS.[279] Osmotic fragility is also improved. The masking effect is observed in both vitamin B_{12} and folate deficiencies and is rapidly reversed after correction of the nutritional deficit.

Obstructive Liver Disease

When obstructive jaundice develops, spherocytosis and osmotic fragility transiently improve and hemolysis abates.[170] This is due to the expansion of red cell membrane surface area that follows the increased uptake of cholesterol and phospholipids from the abnormal plasma lipoproteins that are released by the obstructed liver. In normal cells, this increase in surface area leads to the formation of target cells, but in spherocytes, it leads to the appearance of discocytes. For example, we have seen a 6-year-old child who developed jaundice and symptoms of biliary obstruction. She had a palpable spleen tip, evidence of mild compensated hemolysis (hemoglobin concentration of 14 g/dL; reticulocyte count of 3.3%), a normal peripheral blood smear, and normal results for an osmotic fragility test (fresh and incubated cells). Abdominal radiographic studies showed calcified stones in the gallbladder and common bile duct. After cholecystectomy and relief of the partial biliary obstruction, the child's hemolysis worsened (reticulocyte count of 10.8%) and she developed anemia (hemoglobin concentration of 10.2 g/dL), spherocytosis, and abnormal results on an incubated osmotic fragility test. She subsequently underwent splenectomy with clinical improvement.

β-Thalassemic Trait

The coexistence of HS and β-thalassemia trait has been described in a few case reports and has been reported to worsen,[282,283] ameliorate,[280,284] or have no effect on the clinical status of the patient. In a large French family with independently segregating HS and β-thalassemia trait, patients with both traits had signs of both diseases: small, hemoglobin A_2-rich, osmotically fragile cells and some spherocytes on peripheral blood smears. However, the HS phenotype in these patients was less severe than that of family members with HS but without β-thalassemia trait.[280]

Hemoglobin SC

Coinheritance of HS and hemoglobin SC disease may exacerbate the hemoglobinopathy.[284] A 15-year-old male with both diseases was much more anemic than his siblings with hemoglobin SC disease and experienced five splenic sequestration crises. However, the two diseases may also disguise each other morphologically. Only a few spherocytes or target cells were evident on the boy's blood smear, and the surface-to-volume ratio of his red cells (and probably their osmotic fragility) was normal. This is likely due to the balancing effects of HS (loss of surface area) and hemoglobin SC (loss of cell volume) on red cells.

Hemoglobin AS

Sickle trait may also be worsened by HS.[285,286] Yang and colleagues[287] reported two patients with the combination who suffered multiple splenic sequestration crises. Splenic infarcts also occur.[287,288] On the other hand, spontaneous regression of HS, presumably due to development of a hyposplenic state, has also been observed in two family members who had HS and sickle cell trait.[289]

Complications

Most patients with HS have reasonably well-compensated hemolysis and are rarely symptomatic. These patients only seek medical attention when complications occur. Complications are generally related to chronic hemolysis and anemia.

Gallstones

The formation of bilirubinate gallstones is one of the most common complications of HS and is a major impetus for splenectomy in many patients. Instances of gallstones occurring in infancy[290] have been reported, but most appear in adolescents and young adults. In a retrospective study of 152 consecutive patients with HS, conducted before the development of ultrasonography, gallstones were detected in only 5% of children younger than age 10 years who were adequately examined and in approximately 50% of HS patients between 10 and 30 years of age (Fig. 16-19).[291] More recent data are similar; about 15% of patients less than 18 years old develop gallstones.[24,292] The increase in the incidence of gallstones after age 30 years parallels the incidence in the general

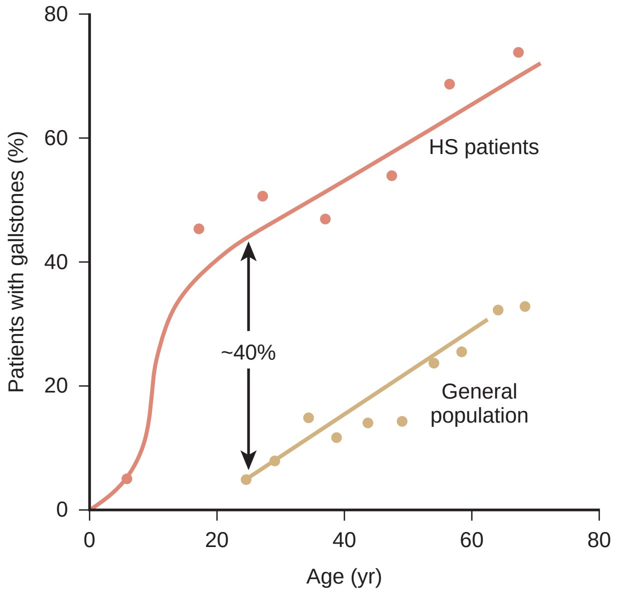

Figure 16-19 Proportion of normal and hereditary spherocytosis (HS) patients with gallstones as a function of age. The graph is redrawn from data in a study of gallbladder disease in 152 consecutive patients seen at The Cleveland Clinic before 1952. Only patients whose gallbladders were examined at surgery or by cholecystography are included. Data for the general population are from an autopsy series of patients who did not have hemolytic anemia. Note that the prevalence of gallstones rises sharply between the ages of 10 and 30 years and parallels the general population after age 30 years. *(Bates GC, Brown CH: Incidence of gallbladder disease in chronic hemolytic anemia [spherocytosis].* Gastroenterology *21:104–109, 1952; Mentzer SH: Clinical and pathologic study of cholecystitis and cholelithiasis.* Surg Gynecol Obstet *42:782–793, 1926.)*

population,[293] which suggests that cholelithiasis owing to HS is primarily manifested in the second and third decades.

The incidence of gallstones in HS patients is related to the ability of the liver to metabolize increased amounts of bilirubin. A common polymorphism in the promoter of the uridine diphosphate-glucuronyl transferase gene (*UGT-1A*) causes decreased enzyme production and, in the homozygous form, causes Gilbert syndrome. Coinheritance of Gilbert syndrome with HS increases the risk for cholelithiasis.[294-297] One retrospective study of 103 children with HS showed that the rate of gallstone formation was 2.2 times higher in those patients with a homozygous mutation in the *UGT-1A* gene than in those with a heterozygous mutation and 4.5 times higher than in healthy patients.[294] HS patients with a homozygous mutation in the *UGT-1A* gene also develop gallstones at a younger age.[298] Therefore analysis of this allele is useful in predicting the risk of cholelithiasis in HS.

Because the pigment stones typical of HS are easily detected by ultrasonography,[294] all patients with HS should have ultrasound examinations about every 5 years if the spleen is intact and just prior to splenectomy. Unfortunately, longitudinal prospective studies using modern techniques (i.e., liver and biliary tree ultrasonography) are not available, making the true incidence and natural history of gallstones in this population unknown. One recent retrospective study showed that patients with HS (or other hemolytic anemias) were much more likely to develop symptomatic disease (i.e., pain, emesis, obstructive jaundice) than children with gallstones for other reasons.[299] In that study, 68% of HS patients with gallstones had symptoms and all of them required cholecystectomy. This coincides with earlier reports.[300,301] The most common complication was biliary obstruction, followed by acute cholecystitis.[299] However, studies that include large numbers of patients with mild HS show a much lower incidence of symptomatic gallbladder disease.[302]

More accurate, longitudinal studies are needed to determine the optimal treatment of patients with mild to moderate HS and cholelithiasis, particularly asymptomatic cholelithiasis that is detected on routine screening. Only about 15% to 20% of adults with asymptomatic stones (all types) develop symptoms over a prolonged period,[303] but the retrospective data above suggest the complication rate may be much higher for bilirubinate stones. Surgery is indicated for recurrent symptoms or signs of biliary obstruction. It is unclear whether children who are undergoing cholecystectomy for symptomatic cholelithiasis should also have a splenectomy or partial splenectomy if it is not otherwise indicated (see later). Most authorities recommend it,[14,304,305] arguing that the risk of stones persists, presumably in the remaining biliary radicals or cystic duct stump. However, cholelithiasis after cholecystectomy for typical gallbladder disease is rare unless a gallbladder remnant remains.[306] Presumably the risk would be higher in someone with continuing hemolysis, but it is not clear how much higher.

If an HS patient requires a splenectomy, an ultrasound study of the gallbladder is indicated prior to surgery to assess the need for concomitant cholecystectomy.[14,307] Cholecystotomy (removal of stones but not the gallbladder) is an option in children with silent stones because the risk of new stones forming is markedly reduced after splenectomy.[308] For this reason, prophylactic cholecystectomy at the time of splenectomy solely to prevent the formation of gallstones is not indicated.[308]

Crises

Patients with HS, like patients with other hemolytic diseases such as sickle cell disease, face a number of potential crises. Table 16-9 summarizes the types of crises that occur in patients with HS.

Hemolytic Crises. Hemolytic crises are probably the most common type in HS. They usually occur with viral syndromes, particularly in children younger than 6 years of age, and are presumed to be due to activation of the reticuloendothelial system.[309] They are characterized by anemia, vomiting, abdominal pain, an increase in reticulocytes, a mild transient increase in jaundice, and tender splenomegaly. Severe hemolytic crises are rare and medical intervention with hospitalization and transfusions is seldom required.

Aplastic Crises. Aplastic crises are less common than mild hemolytic crises but are more serious and may lead to severe anemia, resulting in congestive heart failure or even death.[38] They tend to occur in infants and children.[24]

TABLE 16-9 Classification of Crises

Type	Anemia	Reticulocytes	Jaundice	Cause	Comment
Hemolytic	Increased	Increased	Increased	Viral infections leading to splenomegaly	Frequent, usually mild
Aplastic	Increased	Decreased	Decreased	Parvovirus B19	Occurs once. Severe. Risk to pregnant contacts
Megaloblastic	Increased	No change or decreased	No change or increased	Relative folic acid deficiency	Rare, preventable

Aplastic crises are caused by parvovirus B19, the etiologic agent in erythema infectiosum (fifth disease).[310] Parvovirus B19 infection may present as fever, chills, lethargy, vomiting, diarrhea, and myalgias.[311] Normal children may also develop a maculopapular rash on the face (slapped cheek appearance), trunk, and extremities—the rash of fifth disease—but this is less common in children with hemolysis and an aplastic crisis. In addition, patients with an aplastic crisis experience pallor and weakness from their worsening anemia.[312,313] Jaundice, if present, may decrease as the number of abnormal red cells that can be destroyed declines.

Parvovirus B19 selectively infects erythropoietic precursors and inhibits their growth by inducing apoptosis and cell cycle arrest at G_2.[314-317] Parvovirus infections are often associated with mild neutropenia (≈20%) or thrombocytopenia (≈40%), and instances of transient pancytopenia have been reported.[310,318-320] Parvovirus may infect several members of a family simultaneously.[320-324]

The sequence of events in an aplastic crisis was well described by Owren[312] (though he confusingly called the crisis "hemolytic," reflecting the recovery phase, instead of aplastic) and is illustrated in Figure 16-20. During the aplastic phase, the hematocrit level and reticulocyte count fall, marrow erythroblasts disappear, and unused iron accumulates in the serum. As production of new red cells declines, the cells that remain age and microspherocytosis and osmotic fragility increase. The return of marrow function is heralded by a fall in the serum iron concentration and the emergence of granulocytes, platelets, and, finally, reticulocytes. During this recovery phase, the serum phosphorus can drop to dangerously low levels.[325] Furthermore, the lack of reticulocytes early in the recovery phase should not eliminate hemolytic anemias from diagnostic consideration.

Infection with parvovirus B19 is a particular danger to susceptible pregnant women because it can infect the fetus, leading to fetal anemia, nonimmune hydrops fetalis, and fetal demise.[326-328] The risk of nonimmune hydrops fetalis to the fetus of a woman who becomes infected with B19 during pregnancy is probably low. Nevertheless, because the virus is highly contagious and is easily transmitted to patients and staff[329,330] and because only one half to two thirds of pregnant women have acquired protective antibodies,[331] patients who have or are suspected of having an aplastic crisis should be placed under respiratory and contact precautions while hospitalized and IgG-negative contacts who are pregnant should be tested for evidence of seroconversion. Nonimmune hydrops fetalis can be detected by ultrasonography and treated with intrauterine transfusions.[332]

Many asymptomatic patients with mild HS and compensated hemolysis first come to medical attention during an aplastic crisis.[333-335] It is important to recognize that

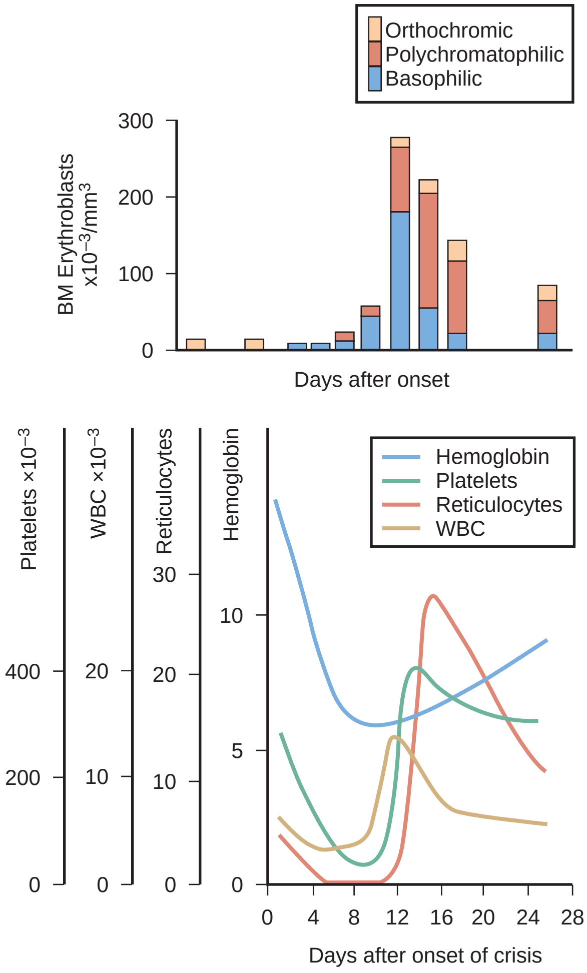

Figure 16-20 The temporal sequence of a severe aplastic crisis in a patient with hereditary spherocytosis who previously had well-compensated hemolysis. Note the profound reticulocytopenia and the mild leukopenia and thrombocytopenia in the early phases of the reaction. Note also that the reemergence of reticulocytes is heralded by the sequential return of peripheral blood granulocytes and platelets and bone marrow normoblasts. *(Data from Owren PA: Congenital hemolytic jaundice: the pathogenesis of the "hemolytic crisis."* Blood *3:231–248, 1948.)*

other family members with HS are susceptible and need to be tested. Diagnostic confusion may arise during reemergence of marrow function, when the physician may mistake an aplastic crisis for a hemolytic one. Because aplastic crises usually last for 10 to 14 days[312] (about one half the life span of HS red cells), the hemoglobin value typically falls to about one half its usual level before recovery occurs. Thus aplastic crises are a serious threat to young children with HS, particularly children with more severe forms of the disease.

The diagnosis of parvovirus can be made using serum PCR or immunologic tests. Bone marrow pathology demonstrates giant pronormoblasts, which are a hallmark of the cytopathic effects of parvovirus B19.[336,337] Treatment is supportive until the aplastic episode self-resolves. For severe anemia, red cell transfusions may be necessary. In immunocompromised patients, intravenous immunoglobulin assists in clearing the virus. Immunity after parvovirus infection is lifelong.

Megaloblastic Crises. Rarely, HS patients may have megaloblastic crises due to folate deficiency. These crises occur in patients whose dietary intake of folic acid is inadequate for the increased needs of the red cell precursors in the bone marrow. Therefore megaloblastic crises typically occur in patients with HS who are recovering from an aplastic crisis or who are pregnant.[62,63] A megaloblastic crisis in pregnancy has been reported as the first manifestation of HS. All patients with moderate to severe HS should routinely receive folic acid supplements (about 1 mg/day) prior to splenectomy to prevent this complication. Folate supplementation is unnecessary in mild HS or in HS following splenectomy except during pregnancy.[14]

Other Complications

Gout and Leg Ulcers. Rarely, adults with HS develop gout,[338,339] indolent leg ulcers,[340,341] or a chronic erythematous dermatitis on the legs.[342,343] Splenectomy appears to be curative.

Extramedullary Hematopoiesis. Adults with HS may also develop extramedullary masses of hematopoietic tissue, particularly alongside the posterior thoracic, lumbar, or sacral spine[9,339,344-349] or in the hila of the kidneys[9] or the adrenal gland.[350,351] These masses may spontaneously bleed, leading to hemothorax.[347] They may also cause spinal cord compression.[349] Surprisingly, these tumors often arise in patients with mild HS, perhaps because they often do not undergo splenectomy, and may be the first manifestations of HS.[346] The masses gradually enlarge and are sometimes mistaken for neoplasms.[339,348] Biopsy may lead to extensive bleeding. If a biopsy is necessary, an open biopsy should be performed. These bone marrow tumors can be diagnosed by magnetic resonance imaging,[352] which may make biopsies unnecessary. The masses stop growing and undergo fatty metamorphosis after splenectomy, but they do not shrink in size.[344,345]

Hemochromatosis. Iron overload is uncommon in HS. Only 4% of unsplenectomized, untransfused HS patients have a serum ferritin greater than 500 ng/mL.[24] However, untreated HS may exacerbate hemochromatosis in patients who are heterozygous for the hereditary disease.[353-356] Several patients with HS subsequently died of liver failure or hepatoma.

Angioid Streaks. These brownish or gray streaks resembling veins in the optic fundus have been described in adult members of several HS kindreds.[357,358] The rate of occurrence of this association is unknown. Angioid streaks are relatively common in some other hematologic disorders, notably sickle cell disease and thalassemia,[357,359] and may be complicated by retinal vascular proliferation that requires treatment.[360]

Pseudohyperkalemia. Because HS red cells leak potassium ions more rapidly than normal red cells, serum samples from HS patients may demonstrate pseudohyperkalemia if allowed to sit for a long period of time before electrolytes are analyzed.[361]

Splenic Rupture. Although splenomegaly is a common symptom in HS patients, cases of splenic rupture are rare.[362,363] In one large recent study, the risk of blunt splenic injury from trauma was only 1 in 20,000 to 50,000 per person per year, a rate that did not differ from the risk in the general population.[363] This contrasts significantly with the splenomegaly that occurs during acute viral infections, such as Epstein-Barr virus, in which splenic rupture occurs with a higher frequency. It is unclear why this difference exists, although it may reflect the unique pathophysiology of splenic enlargement in the different conditions. Children with HS and splenomegaly should not be restricted from normal activities. However, older children and adults with splenic enlargement that extends below the rib cage should probably avoid activities that may inflict a powerful, direct blow to the abdomen.

Nonerythroid Manifestations. Kindreds with HS and neurologic manifestations have been described. In the older literature, multiple case reports describe patients with HS and various neurologic abnormalities, such as a Friedrich ataxia-like disease, cerebellar disturbances, muscle atrophy, and a tabeslike syndrome.[364,365,366,367] More recently, patients with certain ankyrin gene deletions have been reported, who have psychomotor retardation and various neurologic manifestations with or without hypogonadism.[58,106-109,368] Additional reports describe patients with ankyrin-deficient HS and slowly progressive spinocerebellar disease.[364] Erythroid ankyrin and β-spectrin are expressed in the cerebellum and spinal cord, and mice that lack ankyrin develop delayed cerebellar ataxia owing to a slow loss of Purkinje cells.[369] This suggests that selected ankyrin and β-spectrin mutations may affect the neurologic system in addition to red blood cells.

A three-generation Russian family with co-segregating HS and hypertrophic cardiomyopathy has been described,[370] and two brothers have HS, a movement disorder, and myopathy.[371] These cases are interesting because the erythroid forms of spectrin and ankyrin are known to be expressed in muscle.

Splenectomy

Splenectomy cures all but the most severe cases of HS, eliminating anemia and hyperbilirubinemia and reducing the reticulocyte count to nearly normal levels (1% to 3%). In most patients, red cell survival becomes normal or remains only slightly shortened. Spherocytosis and altered osmotic fragility persist, but the "tail" of the osmotic fragility curve, created by conditioning of a subpopulation of spherocytes by the spleen, disappears. After splenectomy, patients with the most severe forms of HS still have some hemolysis, but their clinical improvement is striking.[31,60] Splenectomy appears to have a more beneficial effect on the deformability of spectrin/ankyrin-deficient erythrocytes than band 3–deficient erythrocytes.[372]

Currently, the major decisions about treatment are who should have a splenectomy, what kind of operation should be performed, and how patients should be cared for postoperatively. The indications for splenectomy have to be weighed carefully because a small fraction of patients will die of overwhelming postsplenectomy infections.[373-377,378,379] Because the risk of postsplenectomy sepsis is very high in infancy and early childhood, splenectomy should be delayed until the age of 5 to 9 years if possible and to at least age 3 years in all children, even if transfusions are required chronically in the interim. There is no evidence that further delay is useful, and it may be harmful because the risk of cholelithiasis increases substantially after age 10 years (see Fig. 16-19).[291]

Risks of Splenectomy

Immediate Postsplenectomy Complications. Early complications of splenectomy include local infection such as a subphrenic abscess, bleeding, and pancreatitis due to intraoperative injury to the tail of the pancreas.[380]

Postsplenectomy Sepsis. Overwhelming serious bacterial infection with encapsulated bacterial organisms is one of the most significant risks of splenectomy. The risk is highest with encapsulated organisms, such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*. Postsplenectomy sepsis can be rapidly fatal, and it is unclear how the risk of postsplenectomy sepsis changes over time. Some studies have suggested that the risk is highest immediately after splenectomy, and decreases over time. Other studies conclude that the risk of sepsis is present indefinitely after splenectomy.[377-381]

It is difficult to estimate the risk of postsplenectomy infections after infancy.[382] The surveys of Schwartz and colleagues,[376] Green and coworkers,[373] and Schilling[377] are limited to adults and largely predate immunization for *S. pneumoniae* and other bacteria. These surveys show an incidence of fulminant sepsis in adults of 0.2 to 0.5 per 100 person-years of follow-up and a death rate of about 0.1 per 100 person-years. Three of the four deaths in the Schilling study occurred 18 years or more after the operation, and none of the patients who died had received pneumococcal vaccine or prophylactic antibiotics. In addition, other serious bacterial infections (e.g., pneumonia, meningitis, peritonitis, and bacteremia) in adults were much more common (4.5 per 100 person-years) than normal, particularly in the first few years after the operation. The incidence of postsplenectomy sepsis appears to be higher in children, particularly younger children.[378,379,382-385]

Unfortunately, the majority of studies of postsplenectomy sepsis in adults and children have serious methodologic problems. Most are case reports or retrospective reports subject to recall bias. The patients included in the studies have heterogeneous diseases and have often undergone splenectomy for a variety of indications. Furthermore, in most of the studies, the adult patients are not fully immunized and do not receive antibiotic prophylaxis. Further research is necessary to quantitate the risk over time of postsplenectomy sepsis in HS patients treated according to current practice guidelines.

With the development of the *Haemophilus influenzae* type B conjugate vaccine, meningococcal conjugate and nonconjugate vaccines, and pneumococcal conjugate and nonconjugate vaccines, the risk of postsplenectomy sepsis should be reduced. However, Grace found that only 26% of adults with HS who were splenectomized prior to 1990 had received all of these vaccines and most did not continue to take their antibiotic prophylaxis as adults.[386] A second study came to similar conclusions.[387] Few patients were adequately educated about antibiotic prophylaxis and fever management. These studies highlight the necessity for quality improvement in the care of HS patients after splenectomy.

Babesiosis and Malaria. Splenectomized HS patients are at increased risk for serious parasitic infections, such as babesiosis[388-390] and malaria.[391,392] Babesiosis is a zoonotic infection in which an intraerythrocytic protozoan is transmitted by ticks; the vector is endemic in Europe and in the northeastern, upper Midwestern, and coastal northwestern United States.[393] Babesiosis can also be transmitted by transfusion. About 20 cases per year are reported.[394] In the United States, the etiologic agent of babesiosis is *Babesia microti*. The clinical symptoms usually begin with chills, anorexia, and fatigue and are followed by intermittent fever and symptoms including myalgias, arthralgias, headache, and vomiting.[393] In healthy patients, the infection is often asymptomatic or mild. In patients with asplenia, severe illness with hemolytic anemia can occur, including fulminant illness resulting in death. Diagnosis is made through microscopic identification on Giemsa- or Wright-stained thick or thin blood smears. Serologic tests for *Babesia* antibodies and PCR are also available. Because the primary vector for the parasite is the *Ixodes scapularis* tick, which can also transmit diseases such as Lyme disease and granulocytic anaplasmosis (previously called granulocytic ehrlichiosis), these infections should be considered as well.[393] Current treatment for severe babesiosis uses clindamycin and oral quinine for 7 to 10 days.[393] Azithromycin and atovaquone are effective in milder disease. Exchange blood transfusions should be considered for severely ill patients, especially those with parasitemia of more than 10%. Splenectomized HS patients,

TABLE 16-10 Risk of Adverse Vascular Events Years after Splenectomy for Hereditary Spherocytosis

	Cumulative Incidence of First Event by Age 70[*]	Hazard Ratio[†]	95% Confidence Interval	P-value

[§] Venous events include thrombophlebitis, deep vein thrombosis, and pulmonary embolism.

when traveling in endemic areas, should attempt to avoid tick bites by wearing long pants and using tick repellants.

Animal experiments demonstrate that the spleen is essential in eliminating malaria parasitemia,[395] and human observations show that in the absence of the spleen parasitemia is greater and more mature parasites (schizonts and trophozoites) are observed in the peripheral blood[396] (reviewed[391]). However, only anecdotal reports or small series exist that demonstrate an increased risk of *Plasmodium falciparum* and *Plasmodium vivax* malaria in asplenic individuals, some of whom had unusually severe disease and others of whom did not.[392,397-400] This may reflect the fact that in previously immune patients the spleen is almost nonessential for protection against severe malaria.[392] We conclude that the risk of malaria in splenectomized individuals is not well documented. Nevertheless, the author knows experienced hematologists practicing in areas endemic for malaria who will not allow their patients to be splenectomized. This "local knowledge" suggests the risk is higher than the limited number of reports indicates. Accordingly, we believe that splenectomized HS patients should strictly adhere to malaria chemoprophylaxis when traveling in endemic areas or avoid such areas altogether, and should immediately seek medical advice if a fever develops.

Thrombosis and Thromboembolic Diseases. Many studies demonstrate an increased risk of thrombosis in splenectomized patients where hemolysis persists after the operation,[277,401,402] but it is not clear to what extent this risk applies to patients with HS. Major large-vessel and organ thrombosis is a common finding in murine models of severe HS,[403,404] but thrombotic complications are rare in the milder forms of HS that are typical in humans, at least in the short term. Several studies from Schilling indicate that there is a risk in human HS as well, but it is not manifest for decades.[405,406,407,408] Schilling has a unique experience, with up to five decades of follow-up of a cohort of 634 HS patients. His observations are summarized in Table 16-10.

First, splenectomized HS patients have a significantly increased risk (threefold) of venous thrombotic events compared with normals.[407] These included episodes of thrombophlebitis, deep vein thrombosis, and pulmonary embolism. There is also a modest (1.5-fold) but not quite statistically significantly increased risk of arterial events such as myocardial infarction, stroke, coronary artery disease requiring surgery, and carotid artery disease requiring surgery compared with normals.[407] By age 70 years, 32% of men and 22% of women have experienced an arterial event and about 20% of each gender have had a venous event (see Table 16-10). These numbers are two to five times greater than in normal family members. In HS patients splenectomized in childhood or adolescence, venous thrombotic events begin to occur after age 30 years but arterial complications do not increase significantly until 55 to 60 years of age.[407] The incidence of arterial events occurring following splenectomy shown in Table 16-10 is comparable to the 1.86-fold greater incidence of death from ischemic heart disease following splenectomy that Robinette and Fraumeni observed in an excellent case-controlled study of the outcomes of World War II battlefield splenectomies after three decades.[409]

A few instances of pulmonary hypertension have been observed in HS patients years after splenectomy.[408,410-413] Pulmonary hypertension is a known complication of splenectomy for other reasons, including nonhemolytic conditions such as Gaucher disease,[277,411,413-418] but it was not unusually common in Schilling's long-term study of HS patients,[407] which corresponds to the recently reported experience of Crary et al[419] and the unpublished experience of R.F. Grace at Boston Children's Hospital. Portal vein thrombosis,[402,420,421] priapism,[422-425] and osteonecrosis[426] also seem to be more prevalent after splenectomy for conditions such as thalassemia and Gaucher disease but do not seem to be a complication of splenectomy for HS.

The most interesting and surprising finding in Schilling's studies is that HS patients who avoid splenectomy have about fivefold *fewer* arterial events than *normals* and sevenfold fewer events than HS patients who have had their spleens removed (see Table 16-10).[406,407,427] This is probably because they have lower hemoglobin levels and higher bilirubin levels than normal. A low hemoglobin level is known to correlate with a lower risk of myocardial and cerebral infarction in the Framingham study.[428,429] This may be because anemia of all types is associated with a low cholesterol level.[430-432] This fact has been known for over 100 years[433] but is little studied, is not understood, and has largely been forgotten. Whether the lower cholesterol level accounts for all of the vascular benefits of a low hemoglobin level is not known. Homocysteine concentrations rise after splenectomy for HS and may also be a contributing factor.[432] Higher bilirubin levels also correlate with a low risk of coronary artery disease,[434] perhaps because bilirubin is an antioxidant. It is possible that this benefit accounts for the prevalence of the Gilbert polymorphism.

Thus most of the sevenfold increased risk of deleterious arterial events following splenectomy in HS seems to result from relief of the anemia and hemolysis, whereas most of the threefold increased risk of venous thromboembolism seems to be due to the splenectomy itself (see Table 16-10). The factors potentiating thromboembolism are not well understood. Potential factors include (1) a chronically high platelet count, (2) decreased splenic clearance of free hemoglobin, which decreases serum nitric oxide and potentially causes vasocontriction, and (3) diminished splenic clearance of "blood dust" (microvesicles released from HS red cells and platelets). These particles are assumed to have phosphatidylserine exposed on their surfaces, thus activating the clotting cascade.

Although the vascular risks of splenectomy in HS observed by Schilling need to be confirmed by others, a conservative approach to splenectomy is supported by the available data. It is not clear to what extent polymorphisms that are known to raise the risk of hypercoagulation may contribute to the risks imposed by splenectomy, disorders such as factor V Leiden polymorphism, antithrombin III deficiency, deficiency of protein S or C, and the prothrombin G20210A mutation (see Chapter 33), but it is reasonable to assume they do contribute and incorporate them into the decision making as to whether a splenectomy is indicated or not. Further, once a patient with HS has been splenectomized attempts should be made to limit additional hypercoagulable risk factors.

Indications for Splenectomy

Splenectomy should only be performed if there are clear indications. All patients with severe spherocytosis, who are transfusion dependent or have growth failure or skeletal changes, should undergo splenectomy. Full or partial (subtotal) splenectomy (see later section) is also usually recommended for patients with moderate HS if they suffer from reduced vitality or physical stamina due to anemia; if, later in life, anemia compromises vascular perfusion of vital organs; or if leg ulcers or extramedullary hematopoietic tumors develop. Whether asymptomatic patients with moderate HS should have a splenectomy remains controversial. Partial splenectomy may also be indicated in some of these patients. Splenectomy can be deferred, probably indefinitely, in patients with mild HS and compensated hemolysis. In young symptomatic children with HS, splenectomy should be delayed until at least 3 years of age, and, if possible, until age 6 to 9 years of age, due to the risk of infection. In addition, after 6 years of age, the number of febrile infections is reduced, which decreases the frequency of postsplenectomy fever evaluations.

Surgical Procedures

Laparoscopic Splenectomy. When splenectomy is warranted, laparoscopic splenectomy is the method of choice in most centers, even for large spleens.[435-438] The procedure can be combined with laparoscopic cholecystectomy if desired.[304,305,439] Comparisons of the laparoscopic approach to the open surgical approach demonstrate fewer complications, less postoperative discomfort, a quicker return to preoperative diet and activities, shorter hospitalization stays, decreased costs, and smaller scars in the laparoscopic group.[439-445] The drawbacks of a laparoscopic approach are longer operative time, potentially greater difficulty in controlling bleeding, and capsular fracture with subsequent splenosis.[446] Recent innovations include doing the entire laparoscopic procedure through a single incision, which decreases pain and improves the cosmetic result.[444] Nearly all recent studies support the laparoscopic approach to splenectomy as the method of choice in centers in which the surgical staff is experienced.

Partial (Subtotal) Splenectomy. The emergence of antibiotic-resistant pneumococci and increasing evidence suggesting an increased risk of thrombosis after splenectomy has led to reexamination of the role of alternate treatment modalities. Partial splenectomy has been suggested for selected patients with HS and other hematologic conditions.[447,448,449-451] The goal of the operation is to decrease hemolysis while maintaining residual splenic phagocytic function. In practice, at least 80% to 90% of

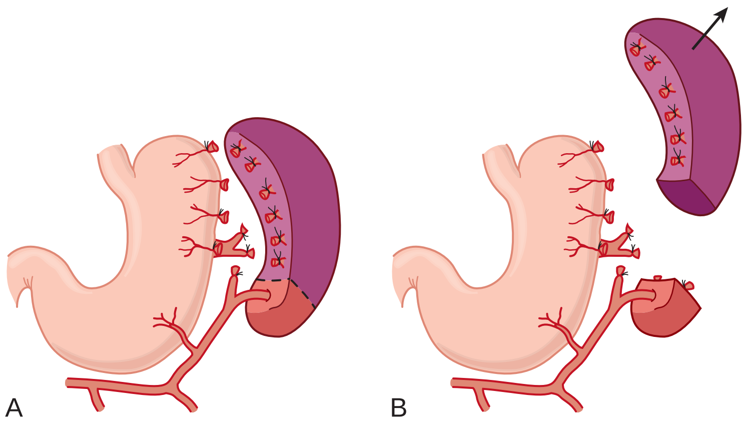

Figure 16-21 Surgical technique used for partial or subtotal (≈80%) splenectomy. **A**, All vascular pedicles supplying the spleen are divided, except those arising from the left gastroepiploic vessels. **B**, The upper pole of the spleen is removed at the boundary between the well-perfused and poorly perfused tissue. *(Modified from Tchernia G, Gauthier F, Mielot F, et al: Initial assessment of the beneficial effect of partial splenectomy in hereditary spherocytosis.* Blood *81:2014–2020, 1993.)*

the enlarged organ is removed (Fig. 16-21). Partial splenectomy was initially an open operation, but laparoscopic and robotic approaches have been developed and are becoming more common.[452-455] The procedure is more time consuming than a total splenectomy and the time for recovery is longer (4 to 7 days of hospitalization), but studies have shown that partial splenectomy is safe and reduces the rate of hemolysis.[447-450,456-458]

Tchernia and colleagues followed 40 patients for up to 12 years after partial splenectomy and found that the mean hemoglobin value increased from 9.2 g/dL to 12.7 g/dL and the absolute reticulocyte count decreased from 523×10^9 cells/L to 267×10^9 cells/L (Fig. 16-22).[448] In the children with at least 10 years of follow-up, no differences in hemoglobin and reticulocyte levels were noticed between the group with partial splenectomy and the group with total splenectomy. Significant splenic regrowth was seen in the first year after partial splenectomy, but, after an initial period, the rate of splenic growth, in this study, was much reduced (see Fig. 16-22, C). Nevertheless, 8% of patients in this study required a total splenectomy after the partial splenectomy, particularly those with severe HS, because of splenic regrowth and resumption of hemolysis. Moreover, 4 of 18 patients in whom the gallbladder was not removed with the initial surgery, required a subsequent cholecystectomy.[448] In a more recent multiinstitutional study of 62 children with a partial splenectomy for HS, only 5% had recurrent hemolysis requiring reoperation and complete splenectomy.[449] Although these results are encouraging, the percentage of HS patients who will require reoperation many years after a partial splenectomy will not be known for several more decades. This is the major risk of the procedure.

A major argument for partial splenectomy is the expectation that patients will be less susceptible to severe sepsis or thromboembolic complications if some splenic tissue remains. This seems logical and is probably true but is impossible to prove without a very large study over a very long time. We are not aware of any reports of overwhelming sepsis following partial splenectomy, and there is some evidence that the risk of sepsis is less.[459] Experimentally, animals are better protected from bacterial challenge if some splenic tissue remains,[460,461] though not as well protected as normal animals,[461] and animals and humans recover immune function more rapidly after partial instead of complete splenectomy.[462,463]

In summary, we believe partial splenectomy is an effective procedure in patients with moderate HS, largely ameliorating hemolysis and anemia while preserving some splenic function. It is important for patients and families to realize that long-term follow-up is encouraging but limited and that splenic regrowth may eventually require a reoperation. For this reason, the procedure cannot yet be recommended as the preferred approach. Some believe that partial splenectomy is the best option for infants with transfusion-dependent HS, who would otherwise be transfused for 3 to 4 years before a complete splenectomy would be done. In such children it is likely that a complete splenectomy will still be needed, however.

Embolization. A few case reports have reported partial splenic arterial embolization as an alternative to splenectomy to treat hemolysis in patients with HS.[464,465] Because the experience with this procedure is limited, it cannot be recommended as routine therapy.

Postsplenectomy Changes

After splenectomy, spherocytosis persists but conditioned microspherocytes disappear, and changes typical of the postsplenectomy state, including Howell-Jolly bodies, target cells, siderocytes, and acanthocytes, become evident in the peripheral blood smear. On average, the MCV and mean red cell surface area increase and the MCHC and osmotic fragility decrease, but the effects are modest (5% to 10%).[466] In typical dominant HS, reticulocyte counts fall to normal or nearly normal levels,[31] although the red cell life span, if carefully measured, remains slightly shortened (96 ± 13 days).[174] In all but the most severe occurrences, anemia and jaundice remit and do not recur.

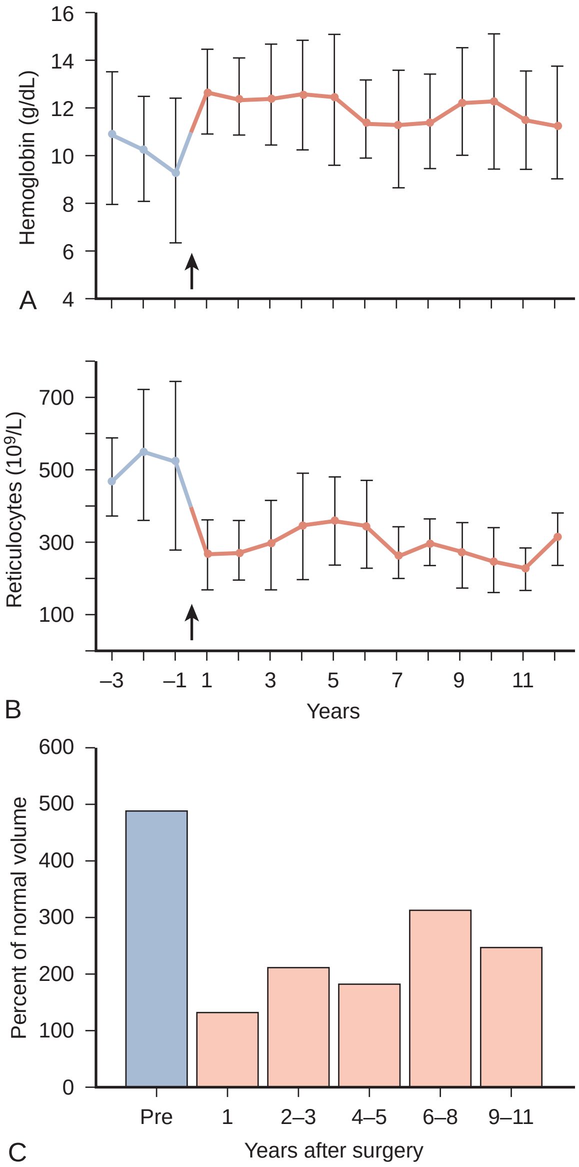

Figure 16-22 Long-term follow-up of partial splenectomy in hereditary spherocytosis (HS). The data are the results of 12 years of experience with the procedure in 40 patients (ages 1 to 25 years). **A** and **B**, Change in hemoglobin and reticulocyte count with time before and after the subtotal splenectomy *(arrow)*. The mean and standard deviations are shown. Both the rise in hemoglobin and fall in reticulocytes have been sustained for more than a decade. **C**, The size of the spleen during the same period. There is some regrowth of the splenic remnant, especially in the first few years. It remains to be seen whether the remnant reaches a stable size or continues to grow. *(Modified from Bader-Meunier B, Gauthier F, Archambaud F, et al. Long-term evaluation of the beneficial effect of subtotal splenectomy for management of hereditary spherocytosis.* Blood *97:399–403, 2001.)*

Splenectomy Failure

The rare splenectomy failure (i.e., recurrence of hemolysis) is usually caused by an accessory spleen that was missed during surgery[456,467] or by another red cell disorder, such as pyruvate kinase deficiency.[468,469] Accessory spleens occur in 15% to 40% of patients and must always be sought.[300,301,380] Occasionally they can be in unusual places: in the chest,[470] across the midline,[471] deeper in the abdomen, and so forth. Recurrence of hemolytic anemia years or even decades after splenectomy should raise suspicion of an accessory spleen,[456,467] particularly if Howell-Jolly bodies are no longer evident on peripheral blood smears. The absence of "pitted" red cells with craterlike surface indentations, readily seen by interference contrast microscopy, is also a sensitive measure of recrudescent splenic function.[472,473] The ectopic splenic tissue can be confirmed by a radiocolloid liver/spleen scan or a scan using ^{51}Cr-labeled, heat-damaged red cells.[467,474]

Other Therapies

Corticosteroid Therapy

It has been known since the 1950s that large doses of corticosteroids markedly ameliorate HS in unsplenectomized patients,[212] similar to the effects produced by splenectomy. More recent studies have confirmed this finding.[213,214] Corticosteroids (prednisolone 1 to 2 mg/kg/day or equivalent for 7 days) can be a useful, temporary alternative to splenectomy in controlling severe hemolytic crises.

Vaccination

All candidates for splenectomy should receive a complete series of vaccinations against encapsulated organisms, including pneumococcus, meningococcus, and *Haemophilus influenzae*. Yearly influenza immunizations are recommended to reduce the chance of secondary bacterial infections. Recent studies have shown that the majority of adults who were splenectomized as children are not up-to-date with their vaccinations.[386] In a study examining the current cases of overwhelming postsplenectomy infection in the era of pneumococcal vaccines, only 31% of 77 patients with such infection received the pneumococcal vaccine.[387] It is important to emphasize the importance of immunizations to the affected parents of children with HS.

Experts differ somewhat on how to protect patients from infection after splenectomy. Our approach follows the 2014 CDC guidelines for vaccination of children[474a] and adults[474b] with high risk conditions. The guidelines change frequently, so the latest version should be consulted. The recommendations of the British Committee for Standards in Haematology have also been published relatively recently.[474c]

If possible, all vaccines should be given at least two weeks and preferably four weeks before splenectomy.

Pneumoccal Vaccines. All children should receive the 13-valent pneumococcal conjugate vaccine (PCV13, Prevnar 13) beginning at two months in the recommended four-dose schedule.[474a] Between two and six years of age, one or two additional doses of PCV13 should be given to children who will have a splenectomy, depending on how many doses of PCV were given in infancy.[474a] The minimum interval between doses of PCV13 is 8 weeks. After 2 years of age, the 23-valent pneumococcal polysaccharide vaccine (PPSV23, Pneumovax 23) should also be administered, assuming it hasn't been given previously.

PPSV23 immunization should be delayed until at least 8 weeks after PCV13.

For adults and children 6 years and older who have not received both PCV13 and PPSV23, one dose of the missing vaccine(s) should be given. If both are needed, PCV13 should be given first and followed at least 8 weeks later by PPSV23.[474a,474b] If PPSV23 is given first, PCV13 administration must be delayed for at least one year.

A single dose of PPSV23 should be given five years after the first dose and again at 65 years of age.[474a,474b]

***Haemophilus influenzae* Type B Vaccine.** Most children will have received the routine Hib vaccine series and a booster dose prior to the age where splenectomy is considered. Whether fully immunized or not, all patients 15 months of age or older should receive a single dose of a Hib-containing vaccine at least two weeks prior to an elective splenectomy. No studies have been performed on the need for reimmunization, which is not recommended at this time.

Meningococcal Vaccines. All patients over the age of nine months who are undergoing splenectomy should be immunized with one of the meningococcal conjugate vaccines: MenACWY-CRM (Menveo) or MenACWY-D (Menactra).[474a,474b] Both vaccines are targeted at serogroups A, C, W-135, and Y. Serogroups B and X are not covered. Children younger than 19 months of age should receive the four-dose infant series of Menveo. Those 19 through 23 months who have not completed this series should receive two primary doses of Menveo at least three months apart. Adults and children older than two years of age should receive two doses of an MenACWY vaccine at least two months apart. Menactra should not be given until at least four weeks after the completion of all PCV13 doses.[474a,474b] Asplenic children whose primary vaccination occurred before 7 years of age should receive an additional dose of either Menveo or Menactra three years later and then every five years.[474d] Asplenic adults and children whose primary vaccination occurred after 7 years of age should be revaccinated with Menveo or Menactra every five years.[474b,474d]

Antibiotic Prophylaxis

Prophylactic antibiotics after splenectomy are recommended, with emphasis on protection against pneumococcal sepsis (i.e., penicillin V or equivalent, 125 mg orally twice daily in children younger than 5 years of age, and 250 mg twice daily in older children and adults). For those patients allergic to penicillin, erythromycin is recommended. Antibiotic prophylaxis is recommended at least through childhood, and, for teenagers and adults, for at least the first 5 years after surgery.

Some physicians recommend lifelong antibiotic prophylaxis because it is unclear how the risk of postsplenectomy overwhelming infection changes over time. The emergence of penicillin-resistant pneumococci (5% in 1989 to ≥35% in 1997) has led many to reconsider this recommendation, particularly because prior antibiotic use is a risk factor for the development of penicillin resistance in pneumococci.[476] Patients who do not take prophylactic antibiotics should have a supply of oral antibiotics on hand, which they should take immediately should fever higher than 101.5°C develop. They should then seek medical attention immediately.

The risk of infection is decreased in immunized patients, because 50% to 70% of postsplenectomy sepsis is due to *S. pneumoniae* and about 80% of pneumococcal disease is due to strains contained in the two vaccines. However, it is likely that strains omitted from the vaccines will rise in frequency as pathogens due to selection. Further risk reduction would be anticipated from the chronic use of prophylactic penicillin. Nevertheless, the risk cannot be reduced to zero. Postsplenectomy infections occur occasionally in successfully immunized patients,[477-479] and compliance with prophylactic medication regimens is a problem, particularly in teenagers.[480]

The occurrence of penicillin-resistant pneumococci is increasing very rapidly all over the world.[481-483] In some countries, more than one half of all isolates are resistant.[484] In the United States, the prevalence is approximately 35%, but it is much higher in some localities and is rising.[481,483,485] Although most of the strains show some sensitivity to penicillin, some are highly resistant and others are multiply resistant.[485-487] The emergence of these strains will greatly complicate the use of antibiotics for pneumococcal prophylaxis during the next decades.

Folic Acid

Patients with moderate or severe HS should take folic acid (0.5 to 1 mg/day or 5 mg/week orally) prior to splenectomy to prevent folate deficiency. Folate supplementation is unnecessary in mild HS or in HS following splenectomy except during pregnancy.[14]

Animal and Fish Models of Hereditary Spherocytosis and Elliptocytosis

Animal models, such as the well-characterized mouse and zebrafish models, have assisted in our understanding of the pathophysiology of HS. Four types of spontaneous spherocytic hemolytic anemia have been identified in the common house mouse, Mus Musculus[488]: ja/ja (jaundice); sph/sph (spherocytosis) and its alleles (sph^{1J}/sph^{1J} [hemolytic anemia], sph^{2J}/sph^{2J} [now lost], sph^{3J}/sph^{3J}, sph^{4J}/sph^{4J}, sph^{IhJ}/sph^{IhJ}, sph^{2BC}/sph^{2BC}, and sph^{DEM}/sph^{DEM}); nb/nb (normoblastosis); and wan/wan. The nomenclature indicates that anemia is observed only in the homozygous state and that the mutants represent four loci: ja, sph, nb, and wan. All the defects are autosomal recessive and cause severe hemolysis, with spherocytosis, jaundice, bilirubin, gallstones, and hepatosplenomegaly,[489] except in the sph^{DEM}/sph^{DEM} mice, which have hereditary elliptocytosis. Another recessive spherocytic hemolytic anemia has been described in the deer mouse, *Peromyscus maniculatus*.[490] This disorder is less severe and closely resembles the autosomal dominant form of human HS. The spectrin content of deer mouse erythrocytes is reduced by about 20% (unpublished data).

Spectrin Mutants

The ja/ja mutant has a defect in the spectrin β-chain (Arg1160→Stop) and produces no detectable spectrin.[491]

The sph/sph variants lack α-chains but have small amounts of β-spectrin. These mice do not produce α-spectrin either due to decreased synthesis, function, or stability. The sph and sph^{2BC} alleles are frameshift mutations and null alleles.[492,493] Four mutations affect the C-terminus of α-spectrin, which was previously thought to be functionless in erythrocytes: (1) sph^{IhJ} is a null mutation (Q1853Stop) in repeat 18[494]; (2) sph^{3J} contains a missense mutation (H2012Y) in repeat 19, near the C-terminus, that alters splicing and results in premature termination of translation[494]; (3) sph^{1J} allele lacks the last 13 amino acids of α-spectrin[495]; and (4) sph^{4J} is a missense mutation (C2384Y).[494] The latter two mutations are in the C-terminal EF-hand domain. All four mutations show marked spherocytosis, and sph^{4J} does so despite minimally decreased membrane spectrin and normal band 3 levels.[494,495] Thus the amino acids in the C-terminus of the spectrin tail are functionally important and, it turns out, are critical in attaching spectrin to actin.[496] The sph^{DEM}/sph^{DEM} mouse is missing exon 11 and 46 amino acids near the amino terminus of α-spectrin repeat 5. These mice have elliptocytes, spherocytes, and poikilocytes, and, therefore clinically appear to be a cross between HS and hereditary elliptocytosis (see later).[495]

Cardiac thrombi, fibrotic lesions, and renal hemochromatosis are found in *ja/ja* and *sph/sph* mice in adulthood.[403,404,497] Transplantation of the hematopoietic cells from *sph/sph* mice is sufficient to induce thrombotic events in the transplant recipients.[498] In mice with α-spectrin mutations, 70% to 100% experience cerebral infarction.[498,499] Studies of red cell adhesion in these mice demonstrate a tenfold higher adhesion to thrombospondin compared with normal red blood cells and an increased adhesion to laminin.[500] Therefore it is hypothesized that changes in the red cell adhesive characteristics contribute to the thrombotic events in these mice.

Riesling (*ris*) is an induced mutation in zebrafish that results in a nearly bloodless phenotype, which causes severe anemia and congestive heart failure.[163] The *ris* phenotype is caused by a null mutation in β-spectrin. The red blood cells of affected zebrafish are spherocytic rather than elliptocytic, the normal zebrafish red cell shape. Scanning electron micrographs show membrane loss, as in other forms of severe HS.

Ankyrin Mutants

Mice with the nb/nb mutation have a primary defect in ankyrin. This is due to a single-nucleotide deletion leading to a frameshift and premature chain termination in the regulatory region of ankyrin.[501,502] The nb/nb red cells have 50% to 70% of normal spectrin levels but only a trace of ankyrin mRNA and protein.[369,489] This is in striking contrast to ankyrin defects in human HS, in which ankyrin and spectrin levels are comparably depressed.[32,100] Fetal nb/nb mice have no anemia and normal reticulocyte counts at birth,[503] possibly because of expression of ankyrin-related proteins in utero.[74] Mice that completely lack Ank1 mostly die in utero.[504] Those that survive have extreme hemolysis and are severely deficient in β-spectrin as well as ankyrin. However, recently a mouse mutation (hema6) has been identified that results in decreased levels of full-length normal ankyrin and more typical HS.[505] This should be useful experimentally.

The *nb/nb* mice also lack ankyrin in cerebellar Purkinje cells.[369] This leads to an age-related loss of Purkinje cells during the first 5 to 7 months of life and the emergence of cerebellar ataxia.[369] Spinocerebellar degeneration and related syndromes have also been reported in a few adult humans with HS,[364-367] although it is not yet known whether ankyrin is affected.

Band 3 Mutants

Complete deficiency of band 3 was first described in cattle with a recessive form of HS. In cows, homozygosity for a nonsense mutation in the band 3 gene leads to absence of band 3 and protein 4.2.[506] Red cell membranes are unstable and show surface area loss, as demonstrated by invagination, vesiculation, and extrusion of microvesicles. The affected cattle have defective anion transport and a mild acidosis but mild hemolysis in comparison with other band 3–deficient species.

In mice, targeted disruption of the band 3 gene causes a severe spherocytic hemolytic anemia, with exuberant loss of the membrane surface as vesicles, tubules, and myelin forms.[161] Red cell membranes also lack protein 4.2 and glycophorin A.[507] Surprisingly, the content of membrane skeletal proteins and the architecture of negative-stained, spread skeletons is normal or nearly normal.[161] Therefore band 3 appears to be required for stabilizing membrane lipids but not for membrane skeleton assembly. For unclear reasons, these band 3–deficient mice have a significant propensity for thrombosis and often die in the neonatal period.[508]

Another mouse model, *wan/wan*, in a C3H/HeJ background, has a null defect in the band 3 gene.[509] These mice have a severe anemia, which is lethal in the neonatal period. However, when *wan/wan* mice are crossed with wild-type mice of a different strain, *Mus castaneus*, the F2 generation shows variable hematologic severity. The genetic modifier causing this variability in hematologic abnormalities has been localized to a small chromosomal region containing the β-spectrin gene.[509]

Finally, zebrafish with band 3 mutations, associated with the *retsina* (*ret*) phenotype, suffer from severe anemia with a complete arrest in erythroid maturation at the late erythroblast stage.[162] These rare *ret/ret* red blood cells are spherocytic rather than elliptical. Many of these arrested erythroblasts have bilobed nuclei that demonstrate defects in cytokinesis.

Protein 4.2

Mice with targeted deletions of the protein 4.2 gene survive normally and have only mildly spherocytic anemia and hemolysis.[510]

Protein 4.1R

Mice lacking the protein 4.1R gene due to targeted deletion have moderate hemolysis and decreased red cell membrane stability.[511] In addition to lacking protein 4.1R, these mice are also deficient in protein 55, glycoprotein

C, ankyrin, and spectrin. The red cell morphology is remarkable for spherocytic shape, rather than elliptocytic shape, likely related to the spectrin deficiency. Interestingly, the knockout mice exhibit specific neurobehavioral deficits in movement, coordination, balance, and learning that correspond with the selective localization of 4.1R in granule cells of the cerebellum and dentate gyrus.[512] Two zebrafish models with protein 4.1R deficiency have been discovered, merlot and chablis, and these mutants have very severe hemolytic anemia, characterized by spherocytosis and increased osmotic fragility.[160]

Adducin and Dematin

Mice lacking just β-adducin[513] or β-adducin and γ-adducin[514] have a very mild, spherocytic hemolytic anemia. Knockout of α-adducin,[515] which eliminates all three adducins (α, β, and γ), still results in only mild hemolysis and moderate spherocytosis, though slightly more severe than in the β-adducin knockout. Similarly, loss of the headpiece of dematin[516] produces, at most, *very* mild hemolysis. However, mice that lack *both* β-adducin and the dematin headpiece have a severe spherocytic hemolytic anemia that resembles severe HS. The data suggest the various vertical membrane connections involving the actin junctions—4.1R-p55–glycophorin C, 4.1R–band 3, alpha spectrin–4.2–band 3, adducin–band 3, adducin–Glut1, and actin-dematin–Glut1—are largely redundant and only become consequential when more than one is eliminated.

HEREDITARY ELLIPTOCYTOSIS AND HEREDITARY PYROPOIKILOCYTOSIS

Hereditary elliptocytosis (HE) is characterized by the presence of elliptical erythrocytes on peripheral blood smears (Fig. 16-23) and defects in the "horizontal" connections that tie the membrane skeleton together (see Fig. 16-4), particularly mutations that impair spectrin self-association. Clinically, these disorders range from the asymptomatic carrier state to severe hemolysis to death in utero due to hydrops fetalis.

History

HE was first reported in 1904 by Dresbach,[517] a physiologist at Ohio State University, who discovered the condition in one of his histology students during a laboratory exercise in which the students were examining their own blood. This report elicited some controversy, because the student died soon thereafter, leading to speculation that the student actually suffered from incipient pernicious anemia.[518] A number of famous pathologists supported Dresbach's view that the elliptocytosis was a primary disorder,[519] and this view was substantiated during the next two decades by the reports of Bishop[520] and Huck

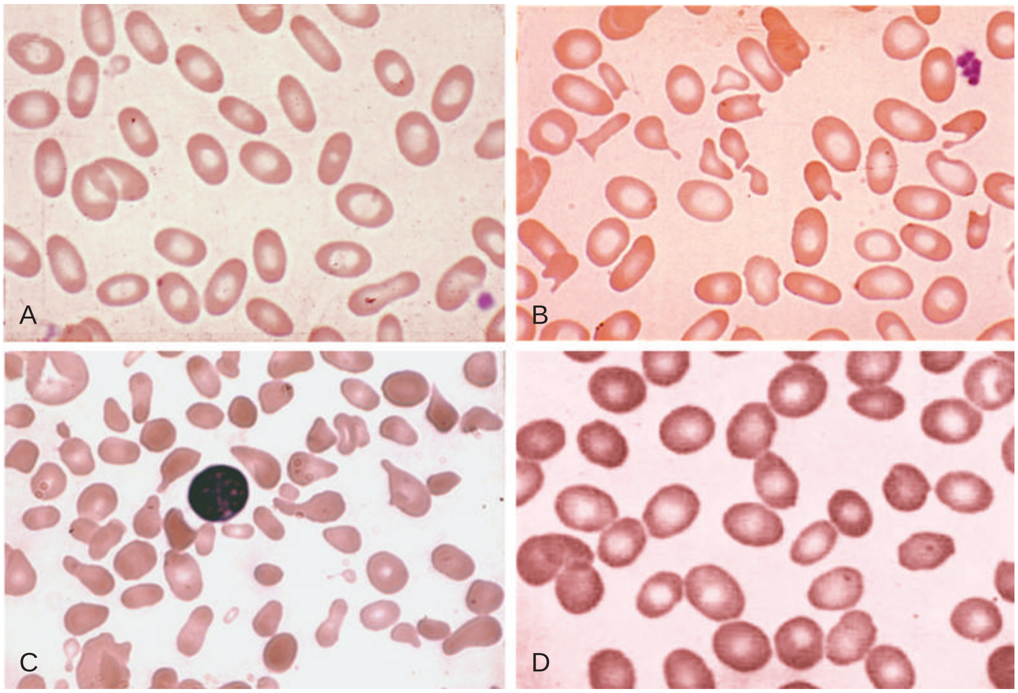

Figure 16-23 Peripheral blood smears from subjects with various forms of hereditary elliptocytosis (HE). **A**, Simple heterozygote with typical HE associated with an elliptogenic α-spectrin mutation. Note the predominant elliptocytosis with some rod-shaped cells and virtual absence of poikilocytes. **B**, HE with infantile poikilocytosis. Note the combination of typical elliptocytes with budding and fragmenting red cells. In some patients the fragmentation is more prominent and may resemble hereditary pyropoikilocytosis. **C,** Severe hereditary pyropoikilocytosis (HPP). Note prominent microspherocytosis, micropoikilocytosis, dense irregular cells, and fragmentation. Relatively few elliptocytes are present. Many poikilocytes are in the process of budding. In patients with less severe HPP, there is less fragmentation and more elliptocytes are evident. **D**, Spherocytic elliptocytosis. Rounded elliptocytes dominate the morphologic picture. The morphologic findings are variable, even within a family, and some patients have more microspherocytes or microelliptocytes than in this example and are more "HS-like."

and Bigelow.[521] The demonstration of the disease in three generations of one family clearly established its hereditary nature.[522,523]

In the 1930s and 1940s, there was some debate about whether HE was a disease or simply a morphologic curiosity.[522-527] Early on, some confusion also existed in the differentiation of HE from sickle cell anemia, from hypochromic elliptocytosis (probably thalassemia), and, later, from HS.[525] These reports emphasize the morphologically deceptive nature of HE and its hemolytic variants. Additional historical features of the disease are found in the reports of Wyandt and associates,[526] Wolman and Ozge,[527] and Dacie.[528]

Prevalence and Genetics

In the United States, HE has been estimated to occur in 1 in 2000 to 4000 of the population.[526,529] The true incidence of HE is unknown because the clinical severity is heterogeneous and many patients are asymptomatic. HE is much more common in areas of endemic malaria, specifically in people of African and Mediterranean ancestry.[159,529-536] The higher frequency of HE in these populations suggests that this disease may confer some resistance to malaria. In a study of HE in Benin, Western Africa, an incidence of 1.6% was observed.[530]

HE variants are inherited predominantly in an autosomal dominant manner. Typically, individuals who are heterozygous for an elliptocytic variant have asymptomatic elliptocytosis without anemia. Individuals who are homozygotes or compound heterozygotes for HE variants may suffer from mild to severe hemolysis with moderate to marked anemia. Spontaneous elliptocytogenic mutations have been reported. Presumably, they are also inherited in an autosomal dominant fashion. In one unique kindred with Alport syndrome, mental retardation, midface hypoplasia, and elliptocytosis, inheritance was X-linked and associated with a submicroscopic chromosome X deletion.[537]

HE is heterogeneous with multiple genetic loci, including reports of mutations in α-spectrin, β-spectrin, protein 4.1R, and glycophorin C genes.[87,88,538-540] Missense mutations in α-spectrin or β-spectrin that produce a functional defect in spectrin self-association are the most common. The mutations described include deletions, point mutations, insertions, and splicing defects. The incidence of one common elliptocytic mutation of α-spectrin, $\alpha^{I/65-68}$, approaches 1% in Central Africa. It has a worldwide distribution in people of African ancestry. Genetic haplotyping studies suggest that this mutation may have a "founder effect," originating in central Africa similar to the Benin type of hemoglobin.[530] This observation further supports the possibility that there has been genetic selection for HE because it imparts some resistance to malaria.[540]

Clinical Syndromes

Most of the reported patients with HE can be classified into one of four clinical categories: typical heterozygous HE, HE with hemolysis/hereditary pyropoikilocytosis (HPP), spherocytic HE, and Southeast Asian ovalocytosis (SAO) (Table 16-11). With the exception of SAO, which is homogeneous in molecular terms and is considered separately (see later), these classifications denote clinical phenotypes and not specific molecular causes, although correlations between the two exist.

Typical Heterozygous Hereditary Elliptocytosis

The clinical characteristics of typical HE trait vary considerably, defining several clinical subtypes. Different clinical patterns may be seen in members of the same family, and the clinical presentation in single individuals may vary over time, so the clinical patterns are probably more useful for illustrating the spectrum of HE than for classifying the disease.

Silent Carrier State. This condition was identified by analyzing asymptomatic members of kindreds with HE or HPP. The affected persons have red cells with normal morphologic characteristics and no evidence of hemolysis, but detailed investigations show a subtle defect in their membrane skeletons, with decreased red cell thermal stability, decreased mechanical stability of isolated skeletons, an increased fraction of spectrin dimers in 0°C spectrin extracts, abnormal tryptic peptide maps of spectrin, or various combinations of these defects.[159,533-536,541,542] Some patients also have α-spectrin^{LELY}, a thalassemia-like splicing defect that impairs production of an otherwise normal α-spectrin protein (see later). It is notable that some patients classified as "silent carriers" have the same molecular defect as patients with mild typical HE,[159,536,542,543] emphasizing the variability of clinical expression.

Typical Hereditary Elliptocytosis (Common or Mild Hereditary Elliptocytosis). This is the most common clinical form of HE.[544-557] Patients are asymptomatic, and HE is often diagnosed incidentally when individuals are undergoing screening for an unrelated condition. These persons are not anemic and rarely have splenomegaly. Red cell survival may be normal,[556] but more often there is very mild, compensated hemolysis with a slight reticulocytosis and decreased haptoglobin level.[548,550,554,558] In these patients, HE is hardly more than a morphologic curiosity. The peripheral blood smear shows prominent elliptocytosis with little red cell budding or fragmentation and no spherocytosis. A subset of patients with more functionally severe defects, usually those most affecting spectrin self-association (see later), have slightly greater hemolysis and anemia together with some red cell fragmentation. Elliptocytes (by definition) usually exceed 30% of the red cells and, in some instances, approach 100% (see Fig. 16-23, *A*).[526,542,543,554,558] Very elongated elliptocytes are common (>10%). These patients are easily separated from normal individuals, who have less than 2% to 5% elliptocytes.[550,552,558] Somewhat higher proportions of elliptocytes are seen in patients with anemias, particularly megaloblastic anemias, hypochromic-microcytic anemias, myelodysplastic syndromes, and myelofibrosis,[559] but even in these individuals elliptocytes do not exceed 35%.[552] Thus the diagnosis of typical HE is rarely difficult.

Typical Hereditary Elliptocytosis with Sporadic Hemolysis. Patients with typical heterozygous HE may develop

TABLE 16-11 Clinical Subtypes of Hereditary Elliptocytosis

Clinical Manifestations	Laboratory Manifestations
Typical Heterozygous HE	
Asymptomatic Dominant inheritance: one parent with HE No splenomegaly Variants: Some neonates with moderately severe hemolytic anemia and HPP-like smear. Converts to typical HE by ≈1 year Some patients with typical HE have mild to moderate chronic hemolysis and some poikilocytosis, due either to coinheritance of the low-expression variant α-spectrin^{LELY}, coexistence of chronic disease producing splenomegaly, or unknown factors	Blood smear: elliptocytes, rod forms, few or no poikilocytes No anemia, little or no hemolysis (reticulocytes = 1% to 3%) Normal osmotic fragility Usually a defect in α-spectrin or β-spectrin leading to decreased spectrin self-association, or a defect in protein 4.1 leading to partial deficiency or dysfunction
Homozygous HE or HPP	
Moderate to severe hemolytic anemia Splenomegaly Intermittent jaundice Aplastic crises Recessive inheritance: typically one parent with HE and one with α-spectrin^{LELY}, or both parents with HE Good improvement after splenectomy	Blood smear: bizarre poikilocytes, fragments, ± spherocytes, ± elliptocytes Reticulocytosis Decreased MCV because of red cell fragmentation Increased osmotic fragility, positive EMA test α-spectrin defects: Decreased red cell and spectrin heat stability Marked defect in spectrin self-association In the more severe variants, partial spectrin deficiency (indicated by more spherocytes on the blood smear)
Spherocytic HE	
Mild to moderate hemolytic anemia Splenomegaly Intermittent jaundice Aplastic crises Dominant inheritance pattern Excellent response to splenectomy	Blood smear: rounded elliptocytes, ± spherocytes. May see variable morphology within a kindred Reticulocytosis Increased osmotic fragility Variable molecular defects: C-terminal truncation of β-spectrin Protein 4.2 deficiency (some patients). Variable morphology: spherocytes, ovalocytes, stomatocytes, or spiculated cells, sometimes resembling spherocytic HE Glycophorin C deficiency (rare)
Southeast Asian Ovalocytosis	
Anemia and jaundice in neonatal period; then asymptomatic Dominant inheritance Lowland aboriginal tribes, especially in Melanesia, Malaysia, and the Philippines Very rigid red cells that resist invasion by malarial parasites in vitro and protect against cerebral malaria in vivo	Blood smear: rounded elliptocytes, some with a transverse bar that divides the central clear space (theta cells) No hemolysis or anemia after neonatal period Normal osmotic fragility, positive EMA test Mutant band 3 that lacks anion exchange function and tends to aggregate, leading to a rigid membrane

uncompensated hemolysis in response to stimuli that cause hyperplasia of the reticuloendothelial system, particularly if the spleen is involved. Examples include viral hepatitis, cirrhosis, infectious mononucleosis, bacterial infections, and malaria.[555,560-562] Hemolysis has also been observed with thrombotic thrombocytopenic purpura and with disseminated intravascular coagulation, which suggests that elliptocytes may be especially susceptible to microangiopathic damage.[563] For unknown reasons pregnancy and cobalamin (vitamin B_{12}) deficiency may also transiently aggravate the disease.[50,564]

Hereditary Elliptocytosis with Infantile Poikilocytosis. Infants with typical HE sometimes begin life with moderately severe hemolytic anemia, characterized by marked red cell budding, fragmentation, and poikilocytosis (see Fig. 16-23, *B*) and by neonatal jaundice, which may require an exchange transfusion.[534,549,558,565-570] Usually enough elliptocytes are present to suggest the diagnosis, but this is not always so and the disorder is mistaken for sepsis, infantile pyknocytosis, or a microangiopathic or oxidant-induced hemolytic anemia.[567,568] HE with infantile poikilocytosis can easily be distinguished from the latter conditions if the parents' blood smears are examined, because one will show typical HE. However, it is more difficult to distinguish HE with infantile poikilocytosis from severe HE or HPP (see later). Many α-spectrin variants have been associated with the infantile poikilocytosis syndrome. The factors that determine susceptibility are unknown. With time, fragmentation and hemolysis decline, and the clinical picture of typical HE emerges.[571] This transition requires 4 months to 2 years.

Subsequently, the disease is clinically indistinguishable from typical HE. The prevalence is unknown, but in our experience, it is unusual but not rare.

The fragmenting neonatal elliptocytes are very sensitive to heat, as are hereditary pyropoikilocytes (see later), but unlike with pyropoikilocytes, this sensitivity lessens over time.[570] During the conversion, the poikilocytic red cells are dense (old) and rich in hemoglobin F whereas the smooth elliptocytes are less dense (young) and enriched in hemoglobin A (unpublished observations). This finding suggests that the change in the disease corresponds to the change from fetal to adult erythropoiesis. No variations in the primary α-spectrin defect or its functional effects on spectrin self-association occur during the conversion, so other skeletal interactions must differ in fetal and adult red cells. Mentzer and associates[572] made the interesting suggestion that 2,3-DPG is the critical agent. Because it is not bound by hemoglobin F, the concentration of 2,3-DPG is elevated in fetal red cells. The free anion is known to weaken spectrin-actin–protein 4.1R interactions[573,574] but the mechanical properties of *normal* red cells or ghosts are not greatly impaired at physiologic concentrations of 2,3-DPG in vitro.[575,576] Whether they are weakened in intact *elliptocytes*, which are more fragile, is untested. If 2,3-DPG does impair spectrin-actin–4.1R binding in situ, the inherited defect in spectrin self-association would certainly be aggravated. However, if this is the explanation it is not clear why only a subset of infants with HE develop infantile poikilocytosis. Perhaps they are the ones with the more functionally severe mutations.[577]

Hereditary Elliptocytosis with Dyserythropoiesis. In a small number of families with otherwise typical HE, the sporadic occurrence of hemolysis and anemia is at least partially due to the development of dysplastic and ineffective erythropoiesis. All the reported patients with this rare syndrome are from Italy. They have somewhat more rounded red cells than is typical for HE plus the characteristic findings of ineffective erythropoiesis: relatively low reticulocyte counts, indirect hyperbilirubinemia, and high serum iron and ferritin concentrations.[578,579] Erythrocytes from some patients are macrocytic. The patients' bone marrows are hyperplastic, with decreased late erythroblasts and dysplastic features (asynchrony of nuclear-cytoplasmic maturation, binuclearity, internuclear bridges, and small numbers of ringed sideroblasts). Anemia and, presumably, erythroid dysplasia usually commence during adolescence or early adult life and advance gradually over years. Splenectomy is not curative for these patients. The available data suggest that dysplasia and elliptocytosis co-segregate because no individuals with dysplasia have been observed who did not also have elliptocytosis.[578,579] These families must have a unique subtype of HE because none of the typical HE protein defects were observed in one well-studied family.

Typical Hereditary Elliptocytosis with Chronic Hemolysis and Hereditary Pyropoikilocytosis

These two conditions are really variations of the same thing: homozygosity or compound heterozygosity for elliptocytogenic mutations and/or silent alleles that augment elliptocytogenic mutations. In general, the greater the hemolysis the more the evidence of membrane instability on the peripheral blood smear: budding red cells, fragments, and other bizarre poikilocytes.

Combination of Typical Hereditary Elliptocytosis with α-Spectrin^{LELY}. Roughly 10% of HE patients have a more severe variant. Sometimes this occurs within members of the same kindred.[547,580-583] It is often due to coinheritance of a very common α-spectrin polymorphism that leads to decreased α-spectrin expression—the α^{LELY} allele—in *trans* to a severely dysfunctional α-spectrin HE allele.[548,577,584-590] The α^{LELY} allele has the effect of increasing the proportion of the HE α-spectrin that is available to combine with β-spectrin and thereby increasing the fraction of defective spectrin on the membrane (see later). Patients with α^{LELY} opposite a severe α-spectrin HE mutation ($\alpha^{LELY}/\alpha^{Severe\ HE}$) have marked hemolysis and elliptopoikilocytosis compared with their siblings with wild-type α-spectrin opposite the same HE allele ($+/\alpha^{Severe\ HE}$), whereas patients with α^{LELY} combined with a mild HE defect ($\alpha^{LELY}/\ \alpha^{Mild\ HE}$) have more elliptocytes than their siblings with $+/\alpha^{Mild\ HE}$ but no significant hemolysis.[587] Less often hemolysis is caused by heterozygous inheritance of a mutant spectrin that is grossly dysfunctional.[580] This is indicated by dominant transmission of the hemolytic syndrome and by an unusually high fraction of spectrin dimers in 0°C spectrin extracts (see later).

Hereditary Pyropoikilocytosis. This uncommon and unfortunately named disorder presents in infancy or early childhood as a hemolytic anemia (hemoglobin level of 2 to 11 g/dL)[558,591-602] characterized by extreme poikilocytosis with budding red cells, fragments, spherocytes, triangulocytes, and other bizarre-shaped cells, as well as, in some patients, few or no elliptocytes (see Fig. 16-23, *C*). The morphologic characteristics of the blood smear somewhat resemble those seen in patients who have severe thermal burns, which explains the name of the disorder. In fact, it is just a severe variant of HE. Most of the patients are individuals of African origin. Patients typically exhibit hyperbilirubinemia in the neonatal period or marked anemia in the first few months of life,[601] but diagnosis may be delayed in milder variants.[603] Red cell fragmentation, erythroblastosis, and splenomegaly are also characteristic.[601,604] Complications of severe anemia, including growth retardation, frontal bossing, and early gallbladder disease, have been reported.[599,600] The red cells are very osmotically fragile, particularly after incubation.[591,598-600] In the most severely affected patients, there is a significant microcytosis, with very low MCVs (25 to 75 fL), because of the large number of fragmented red cells.[159,537,543,558,598,599] Another characteristic feature of these cells is their remarkable thermal sensitivity. Hereditary pyropoikilocytes fragment at 45°C to 46°C (normal 49°C) after short periods of heating (10 to 15 minutes).[600] After splenectomy, hemolysis is markedly decreased, with the hemoglobin level typically ranging from 10 to 14 g/dL with 3% to 10% reticulocytes.[558,599,600]

Some HPP patients are homozygous or compound heterozygous for a structural variant of spectrin, located in the region of the spectrin αβ heterodimer self-association.[558,591-596] Rare patients with homozygous protein 4.1R deficiency have a similar picture.[605] Other HPP patients are compound heterozygotes for an α-spectrin mutation and a silent allele such as α^{LELY} or an even more severe thalassemia-like defect of spectrin synthesis.[606-608] As noted earlier, this thalassemia-like defect enhances the expression of the mutant α^{HE}-spectrin in the cells. An α°-spectrin mutation opposite the α^{HE}-spectrin allele would functionally be the same as having homozygous HE.

Unlike typical HE, HPP red cells are often deficient in spectrin.[558,604,606,607] Presumably if the defect in spectrin self-association is severe enough spectrin either falls off the membrane or never properly assembles. The degree of spectrin deficiency correlates with the severity of HPP and is presumably responsible for the large number of spherocytes and relative paucity of elliptocytes in some patients.

Spherocytic Hereditary Elliptocytosis

This dominant disorder is a phenotypic hybrid of typical HE and HS. It has only been reported in Caucasian families of European descent.[555,609-612] The prevalence of spherocytic HE is unknown, but judging from the number of published reports, it is relatively rare, probably accounting for no more than 5% of HE cases in patients of European ancestry. Unlike in typical HE, almost all affected patients have some hemolysis. This is usually mild to moderate and is often incompletely compensated. The elliptocytes are fewer and plumper than in typical HE (see Fig. 16-3, D), and some spherocytes, microspherocytes, and microelliptocytes are often present. Poikilocytes and red cell fragments are uncommon, a finding that distinguishes this disorder from typical HE with hemolysis. Some spiculated cells may be present following splenectomy,[609] similar to what is seen in β-spectrin deficient HS. Red cell morphologic findings may vary, even within the same family. Some family members may have relatively prominent spherocytes and as few as 10% to 20% elliptocytes, whereas in others elliptocytes predominate and spherocytes are rare.[524,609] This may cause diagnostic confusion initially, particularly if the propositus has few elliptocytes. Family studies almost always reveal some members with obvious elliptocytosis.

Spherocytic elliptocytes are osmotically fragile,[524,609,611,612] particularly after incubation. Gallbladder disease is common, and aplastic crises are a risk.[609,611] The pathologic course of spherocytic HE mimics that of HS.[613-615] Splenic sequestration is evident, red cells are conditioned during splenic passage, and hemolysis abates after splenectomy.[609,611,614]

The molecular pathology of classic spherocytic HE is not well studied. Patients with C-terminal truncations of α-spectrin (see later) have many of the clinical features of spherocytic HE and probably are a subset of the disorder.[616-624] Patients with such truncations typically have moderate hemolysis and anemia, punctuated by recurrent, severe hemolytic crises.[617,618,621] Blood smears show plump and usually smooth elliptocytes, although in a few instances, poikilocytosis was prominent.[617,618,620]

Patients who lack glycophorin C (see later) also have positive osmotic fragility tests and rounded, smooth elliptocytes.[625,626] They should probably also be classified as having a recessive (and unusually mild) variant of spherocytic HE. Patients who lack protein 4.2 (another recessive condition) sometimes display features of spherocytic HE (ovalocytes, spherocytes, stomatocytes)[236,627]; however, protein 4.2 deficiency more often resembles HS, morphologically and pathophysiologically, and is better classified as a variant of that disorder. Mice that lack tropomodulin-1 have mild spherocytic HE that is more spherocytic than elliptocytic.[628] The anemia may be partly compensated by an increase in tropomodulin-3, which is not normally expressed in mature red cells, to about 20% of the normal level of tropomodulin-1. Tropomodulin deficiency has not been identified in humans but should be considered.

Very rare patients appear to be compound heterozygotes for HS and HE. One Turkish girl is a particularly good candidate.[629] Her mother had mild HS and her father most likely had very mild HE, whereas she suffered from a moderately severe hemolytic anemia (hemoglobin level, 8.4 g/dL; reticulocyte count, 24%; bilirubin level, 1.6 mg/dL), with frontal bossing, osteoporosis, splenomegaly, and a mixture of microspherocytes and rounded elliptocytes.

Southeast Asian Ovalocytosis

This condition, which has a unique phenotype, molecular defect, and geographic distribution, is discussed later in this chapter.

Treatment

Typical HE is mild and splenectomy is not required. Serial interval ultrasound examinations, beginning at approximately 6 years of age, to detect gallstones should be performed in patients with brisk hemolysis. Splenectomy to decrease hemolysis, ameliorate anemia, and avoid the formation of bilirubinate gallstones has been the cornerstone of therapy for patients with severe hemolytic HE and HPP. Most practitioners believe that the indications for splenectomy in HS should also be applied to patients with symptomatic HE and HPP. Patients with HE and HPP who have been splenectomized have experienced increased hematocrit values, decreased reticulocytosis, and improvement in clinical symptoms. The risk of thrombosis after splenectomy for HE is unclear, although cases have been reported.[630] If hemolysis is still active after splenectomy, folic acid should be administered daily. Recommendations for antibiotic prophylaxis, immunization, and monitoring during intercurrent illnesses are the same as those noted for HS patients before and after splenectomy.

Neonates with infantile poikilocytosis should be treated as any patient with hemolytic anemia. Phototherapy and exchange transfusions are warranted in neonates with severe anemia and pathologic hyperbilirubinemia. Splenectomy is never indicated in the neonatal period. HE patients with extreme hemolysis should be transfused until they are 2 to 3 years of age, when immunizations are effective and splenectomy can be performed safely. Partial splenectomy is not as effective as in HS.[631]

Laboratory Methods

Thermal Sensitivity of Red Cells and Spectrin

Red cells heated to temperatures approaching 50°C for short periods of time become unstable and fragment spontaneously,[631-633] probably owing to denaturation of spectrin.[634] Normal spectrin denatures at 49°C (10-minute exposure),[634,635] and normal red cells fragment at the same temperature.[600,636] Almost all patients with HPP and some patients with milder forms of HE have thermally sensitive red cells. Red cells from patients with HPP and infants with HE and infantile poikilocytosis fragment after 10 minutes at 44 to 46°C.[570,600] Red cells from some but not all patients with typical HE fragment at 47 to 48°C.[600,635] As expected, purified spectrin from these red cells is also heat sensitive.[634,635] This test is limited because we do not understand, in molecular terms, why specific mutations are thermally sensitive. However, it remains one of the simplest tests available for diagnosing HPP in laboratories that do not specialize in membrane protein analysis.

Abnormal Spectrin Oligomerization

In many patients with HE and all patients with HPP, spectrin dimers are not properly converted to tetramers and higher oligomers in vitro or on the membrane. This important functional property is easily assessed in low-temperature spectrin extracts. At 0°C, the equilibrium between spectrin dimer and tetramer is kinetically frozen. If spectrin is extracted from the membrane at 0°C and carefully protected from warming during separation of dimers, tetramers, and oligomers (usually on nondenaturing polyacrylamide gels), the proportion of each spectrin species reflects its relative proportion on the membrane.[637] Patients with defects in spectrin self-association have abnormally high proportions of spectrin dimer in 0°C spectrin extracts (i.e., more than 10% of total spectrin dimers and tetramers).[582,636,638] The fraction of spectrin dimers is an important functional assessment in patients with α-spectrin defects. It correlates well with clinical severity and accurately predicts unusually severe mutations.[588] Conversely, discordance between the degree of hemolysis and fraction of spectrin dimers may alert the physician to an underlying, secondary complication.

Ektacytometry

The technique of osmotic gradient ektacytometry (OGE) to measure membrane surface area and cell hydration of intact red cells was discussed earlier, in the section on laboratory tests in HS, but the ektacytometer can also be used to assess red cell membrane mechanical stability.[268,269] Isolated red cell ghosts are subjected to high shear stress in a laser diffraction viscometer, and the DI (a measure of the average elongation of the sheared ghosts) is recorded as a function of time. Fragile ghosts fragment into small spheres more quickly than normal, causing their "deformability" to fall. The technique is a useful screening test because membrane stability is reduced in HE and dramatically so in HPP.[268]

Eosin-5′-Maleimide–Binding Test

EMA binds to band 3 and members of the Rh protein complex and is a measure of the amount of these proteins on the red cell surface, and therefore an indirect measure of membrane surface area (see earlier discussion under Hereditary Spherocytosis). Because red cell surface area is greatly decreased by cell fragmentation in HPP, EMA fluorescence is very reduced on a per cell basis, even more than it is in HS.[639]

Tryptic Maps of Spectrin

Limited tryptic digestion of spectrin extracted from erythrocytes, followed by two-dimensional gel electrophoresis, separates the resulting trypsin-resistant domains of α-spectrin and β-spectrin, including an 80-kD α-I domain peptide ($\alpha^{I/80}$) containing the self-association site of α-spectrin.[640,641] Many of the α-spectrin HE mutations reside in this domain and alter its structure so that it is cleaved into smaller fragments by trypsin. These were given names such as $\alpha^{I/74}$ or $\alpha^{I/65\text{-}68}$. Although the technique is historically important it is rarely used now.

Genetic Analyses

Increasingly HE mutations are identified by DNA sequencing. Unlike HS, some of the HE mutations are quite common and their location and nature relate to their clinical severity, so it is useful to know the specific molecular lesion. It is also important to know whether the patient carries the common spectrin α^{LELY} polymorphism and whether it is in cis or trans to the HE mutation because that can greatly affect the clinical picture (see below). Typically exons are amplified from genomic DNA isolated from peripheral blood leukocytes, but because most HE mutations are missense mutations, reverse-transcribed reticulocyte or bone marrow mRNA can also be amplified. At the moment, DNA testing for HS and HE mutations is not available commercially and only a few research laboratories will do the analysis. However, with the rapid fall in the cost of whole-exome and targeted exome sequencing, it is likely these will become the methods of choice in the near future.

Pathophysiology

Spectrin Defects

Abnormalities of either α-spectrin or β-spectrin are responsible for most cases of HE and HPP. The majority are due to missense mutations near the spectrin self-association site (blue symbols in Figs. 16-6 and 16-8). The spectrin self-association contact site is a combined triple helical "spectrin repeat" (see Fig. 15-13 and Fig. 15-14) in which two of the three helices that make up a typical spectrin repeat, helices A and B, are contributed by the C-terminus of the β-spectrin, whereas the third helix (C) comes from the first portion of the NH_2-terminus of α-spectrin. These three helices pair up[533,642,643] and create the bond responsible for spectrin self-association. HE mutations weaken the ability of spectrin dimers to form tetramers and destabilize the membrane skeleton. The functional damage is manifested by an increased proportion of spectrin dimers in 0°C low–ionic strength extracts of spectrin, and by decreased conversion of spectrin dimers to tetramers in solution and on the membrane. The broken spectrin-spectrin links are visible in electron micrographs and diminish the resistance of the isolated membranes to shear stress.[268,536] The clinical severity of HE correlates with the degree of impairment of spectrin self-association and with the amount of mutant spectrin that is produced.

A few examples of mutations that cause HE or HPP follow. Readers who are interested in a more extensive list of HE/HPP mutations can refer to an earlier chapter by the author[83] or to selected reviews,[11,82,540,644] or consult the paid[87] or free[88] versions of the Human Gene Mutation Database.

Alpha-Spectrin Defects Within the Self-Association Binding Site. α-Spectrin mutations account for 48% of the reported defects in HE and HPP.[87] Many of the mutations are located in the C helix at the beginning of the α-spectrin chain (Fig. 16-24 and see Fig. 16-6), which is a partial spectrin repeat, also called spectrin repeat 0 (see Fig. 16-24). Most of these mutations change amino acids that are part of the contact surfaces between the α-spectrin and β-spectrin chains at the tetramerization site and greatly impair or even abolish spectrin-spectrin binding.[643] As a result, they are among the most severe of the common α-spectrin mutations that cause HE and HPP.

Alpha-Spectrin Defects Beyond the Self-Association Binding Site. Mutations that affect spectrin repeats beyond repeat 0 tend to be less severe and some of them are very common. An example is the unnamed duplication of leucine at residue 154 (Leu154LeuLeu or α$^{\text{dup154L}}$; see Figs. 16-6 and 16-24). This mild mutation is widely distributed in blacks in West Africa, where the prevalence of HE is between 0.7% and 1.6%, and in their descendants in the West Indies and North America.[530,531] It is also seen in Arab populations and is the most common cause of HE in North Africa and southern Italy. It causes very mild HE in North Africans, who sometimes have little or no elliptocytosis (i.e., are silent carriers). Even homozygotes have only mild to moderate hemolysis. Another example is α-spectrin$^{\text{Nigerian}}$ (Leu260Pro; see Figs. 16-6 and 16-24), which has an incidence of 0.5% in Benin and Togo.[530,645] It is more severe than Leu154LeuLeu but less severe than most of the mutations located in repeat 0. A similar variant (Leu207Pro) is common among the Dendi people of West Africa and called α-spectrin$^{\text{St. Louis}}$, a low-expressing allele, when it is combined in *cis* with spectrin α$^{\text{LELY}}$. The prevalence of Leu154LeuLeu, Leu260Pro, and Leu207Pro strongly suggests that these mutations have undergone genetic selection[530,645] and may provide some protection from malaria (see later).

Other examples of distal HE mutations include α-spectrin$^{\text{St. Claude}}$, α-spectrin$^{\text{Oran}}$, and α-spectrin$^{\text{Jendouba}}$ (see Fig. 16-24). These recessive alleles are asymptomatic in the heterozygous state but cause HE or HPP when homozygous. α-Spectrin$^{\text{St. Claude}}$ has an incidence of 3% in Benin, Africa.[646] It is a splice junction mutation that yields two mRNAs,[593] one that encodes an impotent, truncated α-spectrin that fails to assemble into the membrane skeleton, and another that encodes a protein lacking exon 20 that binds ankyrin poorly.[647] Homozygotes have a severe poikilocytic anemia.[646] α-Spectrin$^{\text{Oran}}$ is another interesting splicing variant, which deletes exon 18.[592,595] It is expressed at low levels and causes severe HE in the homozygous state.[592]

The mechanism by which the more distal mutations propagate their effects along the α-spectrin chain and interfere with spectrin self-association is beginning to be dissected. One recent study[592a] shows that the common Leu207Pro defect, which lies in the second alpha spectrin repeat, alters the conformation of the first three repeats. The result is a more compact spectrin dimer structure that is strengthened by several new interprotein contacts, reducing the tendency of spectrin to form tetramers. The common Leu260Pro mutation also causes α-spectrin to form a more compact structure than normal and increases

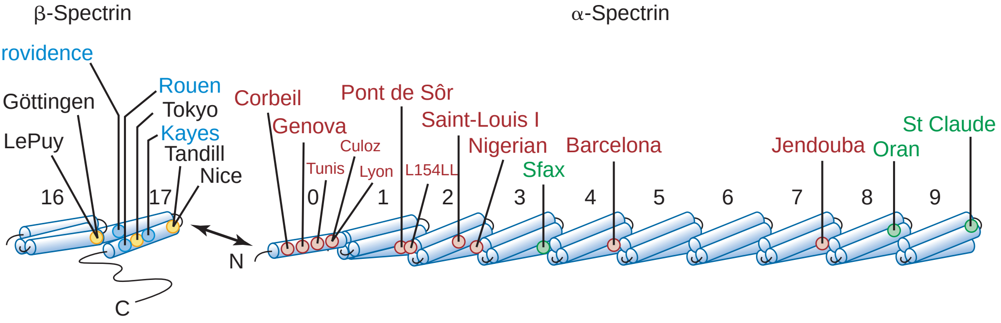

Figure 16-24 Triple-helical model of a subset of the roughly three dozen mutations in α-spectrin or β-spectrin associated with hereditary elliptocytosis (HE) and hereditary pryopoikilocytosis (HPP). Nearly all the α-spectrin mutations are missense mutations or in-frame deletions or insertions *(red circles)* or are splicing defects *(green circles)*. The mutations in the partial spectrin repeats α0 and β17 that comprise the spectrin self-association site tend to be more severe. The mechanism by which the more distal mutations propagate their effects along the α-spectrin chain and interfere with spectrin self-association is unknown. Most β-chain defects are C-terminal trunctations *(blue circles)* or missense mutations directly affecting spectrin self-association *(yellow circles)*. The truncations also impair synthesis of the mutant spectrin and often lead to a spherocytic elliptocytosis phenotype. Common mutations include the unnamed duplication of Leu at codon 154 (L154LL), spectrin Nigerian (L260P), and spectrin St. Claude, a splicing defect.

the stability of the closed dimer state, thereby reducing tetramer formation and destabilizing the membrane.[592b]

Low-Expression α-Spectrin Alleles: α^{LELY} and Related Polymorphisms. An HPP-like clinical picture may result from inheriting two elliptocytogenic genes for either α-spectrin or β-spectrin, but more often it occurs by combining an HE α-spectrin gene with a thalassemia-like defect on the opposite "normal" α-spectrin gene. These patients may also have spectrin deficiency. The parents who transmit the low-expression allele are clinically and biochemically normal. The best characterized of these low-expression alleles is the α^{LELY} allele (low-expression Lyon), which affects approximately 30% of the α-spectrin alleles of Caucasian European patients, 20% of the alleles of Japanese and African patients, and 22% of the alleles of Chinese patients.[587,648] Therefore approximately 42% of Caucasian Europeans are heterozygous for this allele and 9% are homozygous. The genetic advantage of the α^{LELY} allele has not yet been uncovered.

The α^{LELY} allele is caused by a combination of two mutations (Fig. 16-25). The key mutation is a C→T substitution at position −12 of intron 45, immediately upstream of exon 46, which causes the six amino acids encoded by exon 46 to be skipped 50% of the time. The second passenger mutation is in linkage disequilibrium. It is an amino acid substitution, Leu→Val at codon 1857 in exon 40, due to a C→G substitution.[649,650] This mutation alters tryptic cleavage of α-spectrin and creates an increased concentration of the 41-kd αV tryptic peptide, called the $\alpha^{V/41}$ polymorphism.[587]

The α^{LELY} allele is clinically silent by itself, even when in the homozygous state, because α-spectrin is normally synthesized in a fourfold excess.[651] In patients who have α^{LELY} on one chromosome and an α-spectrin mutation causing HE in *trans* on the opposite chromosome, the low expression of α^{LELY} decreases the amount of the otherwise normal spectrin from that allele that is incorporated into the membrane by approximately 50% and increases the relative incorporation of spectrin containing the mutant HE α-chain. α^{LELY} is poorly expressed owing to the mutation in intron 45, described above, which causes defective spectrin nucleation because the six deleted amino acids encoded by exon 46 lie within the nucleation site that joins the α-spectrin and β-spectrin chains.[652,653] α-Chains that lack exon 46 fail to assemble into stable spectrin dimers and are rapidly degraded (see Fig. 16-25).

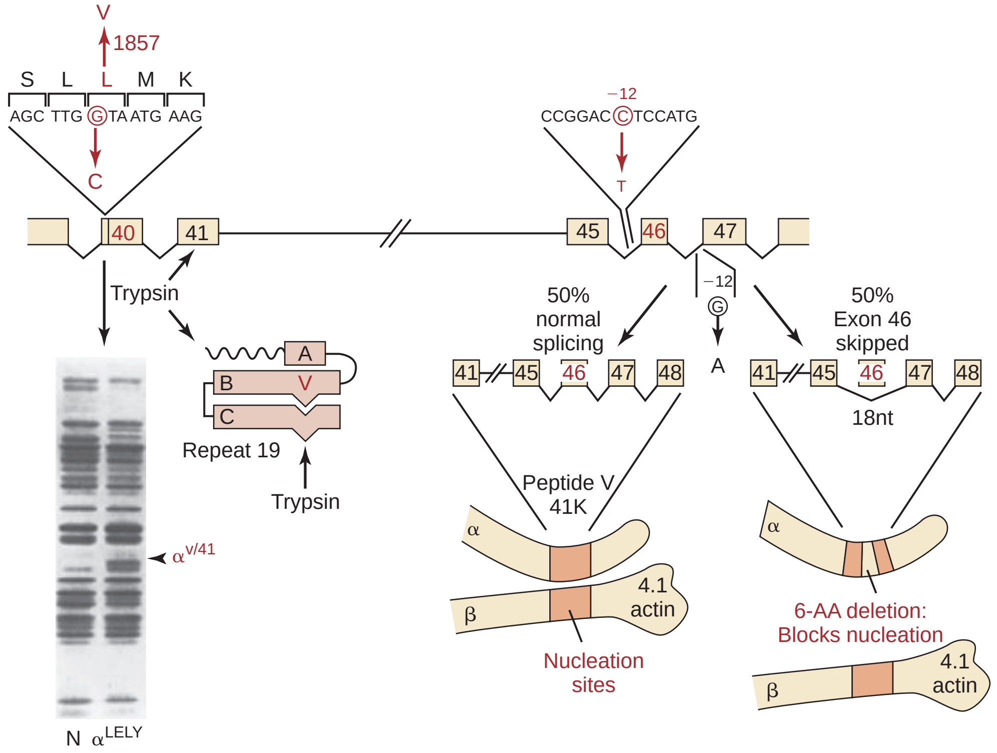

Figure 16-25 Nature of the low-expression α^{LELY} allele. The allele contains two linked mutations: a marker mutation, the $\alpha^{V/41}$ defect, and a splicing mutation, the α^{LELY} defect. *Left*, The $\alpha^{V/41}$ defect is caused by a G→C substitution at the beginning of exon 40, which changes a Leu1857→Val in helix B of spectrin repeat 19. The valine impinges on the neighboring helix C of the repeat and makes it more trypsin sensitive, leading to a more rapid release of the $\alpha^{V/41}$ peptide from the trypsin-treated spectrin derived from the α^{LELY} allele. Sodium dodecyl sulfate gels of trypsin-treated normal spectrin and spectrin containing α^{LELY} are shown at the bottom left. The $\alpha^{V/41}$ peptide is marked. *Right*, The linked splicing mutation is a C→T substitution at position −12 in the acceptor splice site of intron 45 (a second linked mutation G→A, at position −12 of intron 46 may also contribute). This causes exon 46 to be skipped in 50% of α^{LELY} spectrin molecules *(far right)*. Exon 46 is very small, only 6 amino acids, but it lies in the center of the nucleation site required for side-to-side association of the spectrin α and β chains. The half of α^{LELY} spectrin that lacks exon 46 cannot form spectrin heterodimers and is destroyed. Note that the other 50% of α^{LELY} spectrin contains exon 46 and will be functionally normal (though marked by the $\alpha^{V/41}$ tryptic peptide).

The effect of the α^{LELY} allele can be quite dramatic. In one family, a patient who was heterozygous for HE had very mild disease and almost no morphologic abnormality, whereas a relative who had also inherited the α^{LELY} allele in *trans* had severe elliptocytosis.[587] Similarly, in another family, the α^{LELY} allele increased the proportion of mutant spectrin in heterozygotes with a mild form of HE from 45% to 65% of the total spectrin.[587] This was associated with an increase in the proportion of elliptocytes from none or only a few to nearly 100%. Conversely, when the α^{LELY} allele is on the same chromosome as an α-spectrin mutation (i.e., in *cis*), it mutes the elliptocytic phenotype.[535]

The spectrin α^{LELY} should be distinguished from other thalassemia-like defects of α-spectrin synthesis that, when coinherited with some of the α-spectrin mutations, produce a phenotype of HPP. The latter defects are characterized by reduced α-spectrin mRNA levels and diminished α-spectrin synthesis such as occurred in the original HPP patient ($\alpha^{\text{St. Louis II}}$)[607] (see Fig. 16-6) or in two HPP patients who each had a typical HE missense mutation with a null mutation of α-spectrin in *trans*.[608] In contrast, although the synthesis of α^{LELY} subunits is decreased owing to poor incorporation of the peptide lacking exon 46, the production of α^{LELY} mRNA is normal.

A few low-expression alleles have been identified that have a greater effect on α-spectrin synthesis than α^{LELY}. Examples include $\alpha^{\text{St. Louis II}}$, which occurred in the original HPP patient[607] (see Fig. 16-6) and in two other null mutations of α-spectrin.[608] When these are inherited in *trans* essentially all of the spectrin on the membrane contains the mutant HE chains and is dysfunctional. As discussed earlier, three other low-expression alleles, α^{LEPRA}, α^{PRAGUE}, and $\alpha^{\text{Bicêtre}}$ (see Fig. 16-6) cause severe recessive HS and would be expected to augment the effect of a coinherited HE allele, but the combination has not yet been described.

Beta-Spectrin Self-Association Site Defects. Almost 20 mutations in the β-spectrin chain have been associated with HE or HPP (32% of reported HE/HPP defects). These mutations occur at the C-terminal end of β-spectrin (see Fig. 16-8) and tend to be truncations or missense mutations in the partial spectrin repeat (repeat 17) that forms part of the spectrin self-association site (see Fig. 16-24). The truncating defects include frameshift mutations,[618-620,654,655] exon skipping,[616,621-625,656] and a nonsense mutation.[657] Some of the missense mutations directly alter amino acids that form the contact surfaces between α-spectrin and β-spectrin.[643] Others substitute proline residues[658] that disrupt the helices in β-spectrin repeat 17 and indirectly damage spectrin-spectrin binding. Patients with β-spectrin missense mutations have typical HE. However, patients with frameshift mutations leading to truncated β-spectrin have spherocytic HE. Patients who are homozygous for a β-spectrin mutation tend to present with HPP and a more severe clinical course.

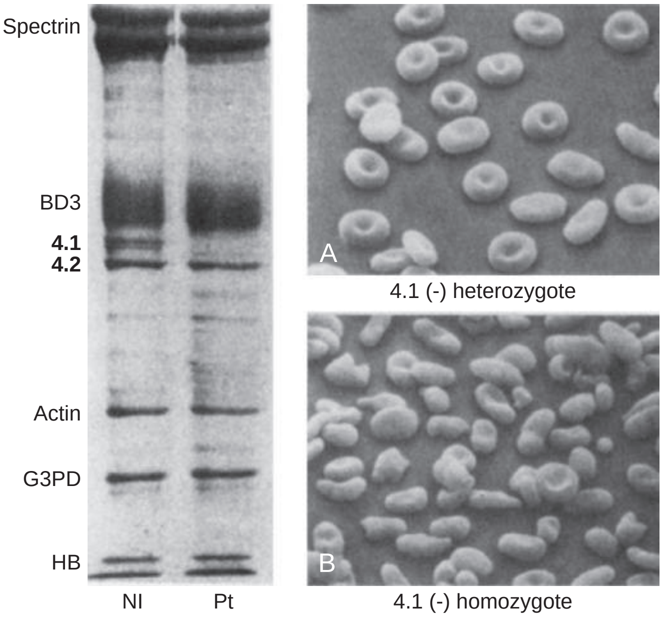

Figure 16-26 Deficiency of protein 4.1R in hereditary elliptocytosis (HE). *Left*, Sodium dodecyl sulfate gels of red cell membrane proteins from a normal individual (*Nl*) and a patient with homozygous HE who lacks protein 4.1R (*Pt*). *Right*, Scanning electron micrographs of red blood cells in 4.1R-deficient patients. **A**, Elliptocytes in a patient with heterozygous HE and 50% protein 4.1R. **B**, Elliptocytes, poikilocytes, and fragmented red cells in a patient with homozygous HE and no 4.1R. *BD3*, Band 3; *G3PD*, glyceraldehyde-3-phosphate dehydrogenase; *HB*, hemoglobin. *(From Tchernia G, Mohandas N, Shohet SB: Deficiency of cytoskeletal membrane protein band 4.1 in homozygous hereditary elliptocytosis: implications for erythrocyte membrane stability.* J Clin Invest *68:454–460, 1981.)*

Protein 4.1R Defects

Approximately 20% of the reported defects that cause HE involve protein 4.1R. The link between protein 4.1R deficiency and elliptocytosis was first described in a consanguineous Algerian family.[605,594] (Fig. 16-26). Partial absence of the protein is found in the 4.1R(−) trait, which appears to be a common cause of elliptocytosis, accounting for 30% to 40% of occurrences in some Arab and European populations.[550,551,659,660] However, this deficiency is not observed in individuals of African ancestry.[531]

In the original Algerian kindred,[605] protein 4.1R(−) mRNA is not translated,[661] owing to a 318-bp deletion, which includes the downstream translation initiation site that is used in reticulocytes (see Fig. 15-18).[662] In other patients, point mutations of the downstream initiator codon have been identified (Fig. 16-27).[594,663,664] Interestingly, expression of protein 4.1R is relatively unimpaired in nonerythroid tissues and early erythroblasts[662] because most of the protein 4.1R isoforms in these tissues initiate translation at an alternatively spliced, upstream translation initiation site.

Protein 4.1R(−) heterozygotes have clinically mild HE with prominent elliptocytosis, often approaching 100%, and little or no hemolysis.[666] These patients have 50% of the normal amount of protein 4.1R.

The very rare homozygous 4.1R(−) patients lack protein 4.1R and have a severe transfusion-dependent, hemolytic anemia with a good response to splenectomy.[605,594,667] Their red cells are elliptical, fragmented,

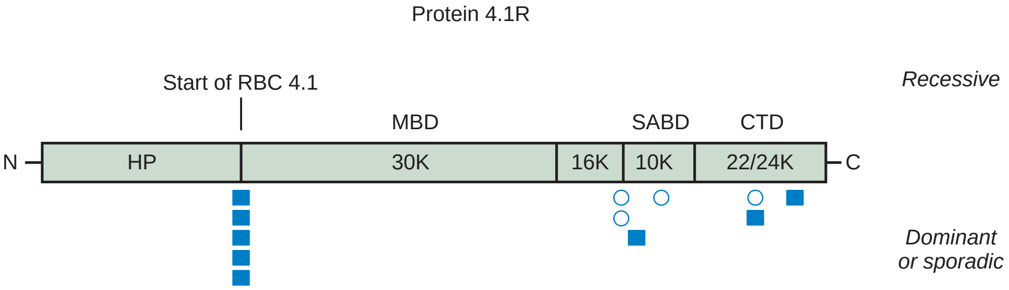

Figure 16-27 Protein 4.1R mutations associated with hereditary elliptocytosis are shown alongside a schematic representation of the protein. Red cell protein 4.1R contains a 30-kD membrane-binding domain *(MBD)*, a 16-kD linker domain, a 10-kD spectrin-actin–binding domain *(SABD)*, and a 22- to 24-kD C-terminal domain *(CTD)*. On the left, four mutations abolishing the translation start site are shown in *solid blue* rectangles. A large deletion and a large insertion affecting the spectrin-actin–binding domain are shown as *open circles*, as is a missense mutation at codon 447. The nucleotide numbers of the mutations are relative to the first nucleotide of the ATG initiation codon, and may differ from the numbering in some published reports.

and poikilocytic, resembling HPP or severe spherocytic HE (see Fig. 16-26, *B*).[605,594,667] They are very osmotically fragile and possess normal thermal stability. Membranes from homozygous protein 4.1R(–) red cells fragment much more rapidly than normal at moderate sheer stresses, an indication of their intrinsic instability.[268] Membrane mechanical stability can be completely restored by reconstituting the deficient red cells with normal protein 4.1R or the spectrin-actin binding site from protein 4.1R.[605,668]

In addition to complete protein 4.1R deficiency, erythrocytes from protein 4.1R(–) homozygotes lack protein p55[669,670] and have only 30% of the normal content of glycophorin C and D.[594,670-672] This strengthens the evidence that glycophorin C is one of the membrane attachment sites for protein 4.1R.[673] Electron microscopic studies of homozygous 4.1R(–) erythrocyte membranes reveal a markedly disrupted skeletal network with disarray of the intramembrane particles, suggesting that protein 4.1R plays an important role in maintaining the organization of integral membrane proteins as well as the skeletal network.[674] Mice that lack protein 4.1R have decreased intestinal calcium absorption due to altered expression of PMCA1b, the plasma membrane calcium ATPase 1b.[674a] This in turn leads to secondary hyperparathyroidism. It's not clear whether the same problem occurs in humans but clinicians should be aware of the possibility.

Protein 4.1R Structural Defects. Variants of protein 4.1R with abnormal molecular weights have also been described in association with HE.[551,675-678] For example, a shortened protein 4.1R that lacks the two exons encoding the spectrin/actin-binding domain was discovered in an Italian family with very mild HE and mechanically unstable red cells. The patients are heterozygous for the mutant protein, which is presumed to be functionally inept. Similarly, a high-molecular-weight variant, protein 4.1R$^{\text{Hurdle-Mills}}$,[551] contains a duplication of three exons that include the spectrin/actin-binding domain and causes very mild HE in heterozygotes.[675,676] Its membrane function appears to be largely preserved because red cell membranes have normal mechanical stability.[679] Other examples of variants of protein 4.1R with abnormal molecular weights have been described.[677,678]

Acquired Protein 4.1R Deficiency. Elliptocytosis with an acquired deficit in protein 4.1R occasionally occurs in patients with myelodysplastic syndromes, particularly in association with a deletion in the long arm of chromosome 20.[680,680a]

Glycophorin C Defects

Elliptocytes are noted on peripheral blood smears of patients whose erythrocytes carry the rare Leach phenotype of Gerbich-negative (Ge–) cells.[625,626,681-686] These erythrocytes are devoid of glycophorin C and glycophorin D and, presumably secondarily, are also deficient in protein p55 and protein 4.1R. It is possible that the protein 4.1R deficiency in Leach erythrocytes is the cause of their elliptocytic shape.

The Leach phenotype is usually due to a deletion of 7 kb of genomic DNA that removes exons 3 and 4 from the glycophorin C/glycophorin D locus.[681,682] Patients carrying the Leach phenotype suffer from mild spherocytic HE with increased erythrocyte osmotic fragility.[625,683-685] In some individuals, no elliptocytes are detected on a peripheral smear.[671]

In contrast to glycophorin C and glycophorin D deficiency, individuals whose erythrocytes lack glycophorin A or glycophorin B, or both, are asymptomatic and have erythrocytes of normal shape and mechanical stability.

Relationship Between Hereditary Elliptocytosis, Hereditary Pyropoikilocytosis, and Spherocytic Hereditary Elliptocytosis

Clinically there is a continuum between the different forms of HE and between spherocytic HE and HS. We hypothesize that there is also a pathophysiologic continuum between these conditions that results from different degrees of loss of spectrin or loss of the spectrin functions involved in holding the membrane skeleton together—specifically, loss of spectrin self-association or the attachment of spectrin to actin with the aid of protein 4.1R (Fig. 16-28).

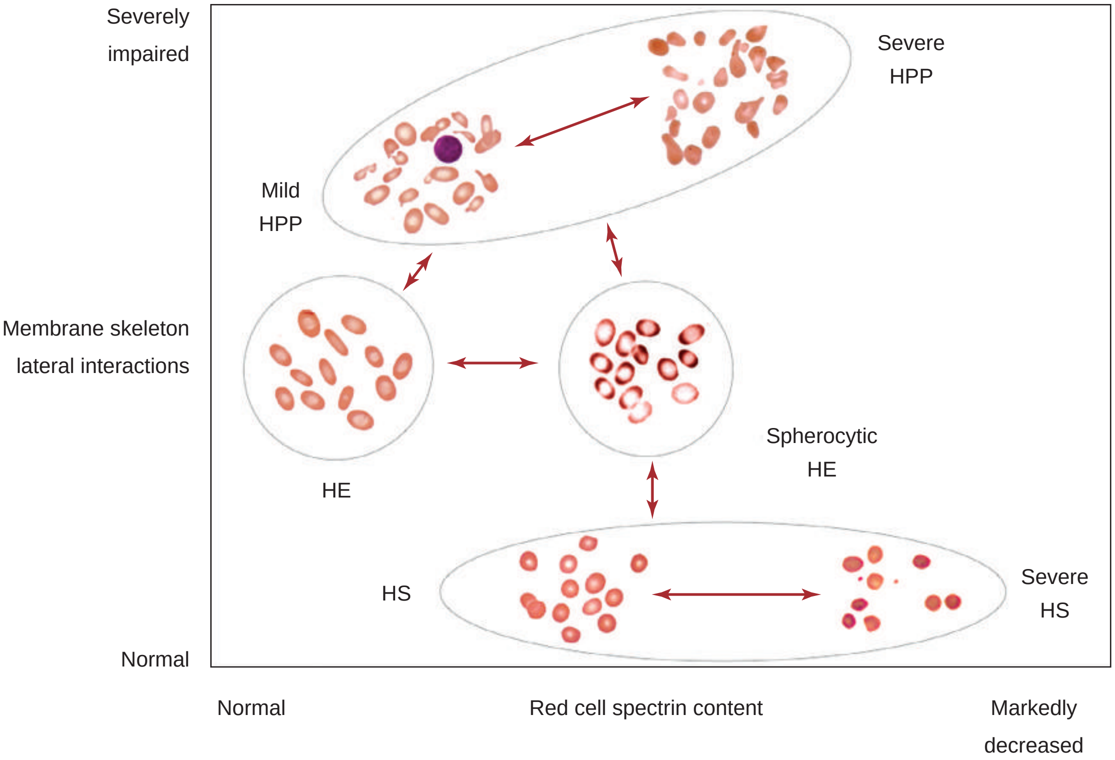

Figure 16-28 Relationships between hereditary elliptocytosis *(HE)*, hereditary pyropoikilocytosis *(HPP)*, hereditary spherocytosis *(HS)*, and spherocytic HE as a function of the degree of spectrin deficiency and the degree of functional impairment of the spectrin self-association or spectrin-actin-4.1R interactions ("lateral" interactions) that hold the red cell membrane skeleton together.

Loss of spectrin without impairment of its function results in HS. Partial loss (≈50%) of either of spectrin's lateral binding functions without loss of spectrin itself leads to typical HE. More severe loss of spectrin binding leads to HPP, but as the functional deficit increases, HPP red cells also tend to lose spectrin from the membrane. This aggravates membrane instability and moves the HPP red cells toward a more spherocytic and less elliptocytic morphology (see Fig. 16-28). It is not clear why spectrin is lost in HPP. It may be that if the proportion of defective spectrin is high enough or the binding defect is severe enough spectrin just cannot bind tightly enough to the membrane to remain attached. Or, it may be that the most deleterious mutations also make spectrin unstable.

Our hypothesis predicts that patients whose heterozygous HE mutation causes the red cells to lose both spectrin content and function will develop spherocytic HE (see Fig. 16-28). Indeed, where measured, spherocytic elliptocytes have been spectrin deficient to a degree similar to that of HS erythrocytes.[624] Spherocytic HE seems to be more linked to mutations that lead to premature termination of β-spectrin than to missense mutations. Shortened molecules would be more likely to be unstable than those with a simple amino acid substitution. Plus, the splicing or nonsense mutations that lead to premature chain termination may trigger nonsense-mediated decay of β-spectrin mRNA. Either process would result in spectrin deficiency.

On the other hand, mutations in α-spectrin would be expected to accentuate loss of spectrin function over loss of spectrin content and lead to HPP rather than spherocytic HE. The reason is because fourfold more α-spectrin is synthesized than β-spectrin. Whether HPP is caused by homozygosity for an HE mutation, or is caused by the combination of an HE defect with a mutation that impairs expression of the "normal" α-spectrin allele, the result is that all or nearly all the spectrin is functionally defective.

Why Elliptocytes?

Why elliptocytes form when the membrane skeleton is weak is less clear. In typical HE, red cell precursors are round and become progressively more elliptical as they age in vivo.[526,552,687] One hypothesis is that the weakened skeletal interactions facilitate skeletal reorganization after prolonged or repetitive cellular deformation and cause red cells to adopt the elliptical shape they sometimes assume when flowing through the microcirculation. However, recent theoretical work argues that the elliptocyte, a biconcave ellipsoid, is the minimum energy shape that the red cell assumes in the absence of shear when the membrane skeleton is weakened.[688]

Hereditary Elliptocytosis and Malaria

The high prevalence of the spectrin $\alpha^{\text{Leu154LeuLeu}}$, $\alpha^{\text{Leu260Pro}}$, and $\alpha^{\text{Leu207Pro}}$ mutations in various tribes of West Central Africa, which is in the range of 0.5% to 1.6%,[530,531,645] suggests that these mutations may have been selected because they provide some benefit against malaria. In fact, in vitro studies show diminished *P. falciparum* parasite invasion or growth in red cells that contain these mutants,[645,689,690] particularly after two to three cycles of growth.[645] Results with protein 4.1R(−) cells were mixed, with one group finding decreased parasite invasion[691] and another group not.[690] Other malarial strains have not been tested and epidemiologic studies have not been done to ascertain whether natives with HE are less likely to be infected or have a milder course.

SOUTHEAST ASIAN OVALOCYTOSIS

Southeast Asian ovalocytosis (SAO) is observed in the aboriginal populations of Melanesia and Malaysia and in portions of Indonesia and the Philippines.[692-698] The abnormality is very common in Melanesia, particularly in lowland and island tribes in whom malaria is endemic,[693,698-701] affecting 1% to 20% of the population.[701-703] It is rare in other populations.[704-707] SAO is inherited in an autosomal dominant pattern.[692-695,699,708] In screening populations where SAO is common, no homozygotes have been identified,[701,709] suggesting that that homozygosity is incompatible with life.

Etiology

SAO is unique among red cell membrane disorders in that all patients have the same defect—a deletion of amino acids 400 to 408 at the beginning of the first transmembrane segment of band 3 (see Fig. 15-7 and Fig. 16-10).[710-715] Many patients also carry an asymptomatic linked polymorphism, Lys56Glu, also known as band 3 Memphis, in cis to the SAO mutation. The mutant SAO band 3 constitutes about half of the band 3 in heterozygotes. It is incorporated into the membrane but is misfolded and is unable to transport anions.[716,717]

Clinical and Laboratory Features

SAO heterozygotes are asymptomatic[692,694,696,697,718] except in the neonatal period. Newborns have significant hemolysis and anemia (the hemoglobin value at 2 days is 14.1 g/dL vs. 16.4 g/dL in normals), and half develop neonatal hyperbilirubinemia,[719] but hematologic values normalize by the age of 2 years.[719] This suggests the mutation uniquely damages fetal red cells. There may be occasional exceptions, as one adult with SAO had compensated hemolysis (no anemia), with mild splenomegaly, hyperbilirubinemia, and gallstones.[720] Homozygous SAO is a near lethal condition. The one known homozygous patient had severe anemia (2.9 g/dL) and hydrops fetalis at 22 weeks gestation. He was saved by intrauterine transfusion and has been transfusion dependent since birth, with distal renal tubular acidosis and marked dyserythropoiesis, especially in late erythroblasts.[720a] The few circulating patient cells were large ovalocytes. The clinical picture is reminiscent of that in zebrafish lacking band 3.[162]

Most SAO red cells are rounded elliptocytes, but a few are traversed by one or two transverse bars that divide the central clear space (Fig. 16-29).[692,696-698,708,718] These "theta cells" are common in SAO (sensitivity 94%) and are rarely seen in normals (specificity 99%) or in other diseases.[718] Thus identification of multiple theta cells on a peripheral blood smear featuring elliptocytosis strongly suggests SAO. Some stomatocytes or elliptical stomatocytes may also be present and the number of hyperdense cells may be increased.[721]

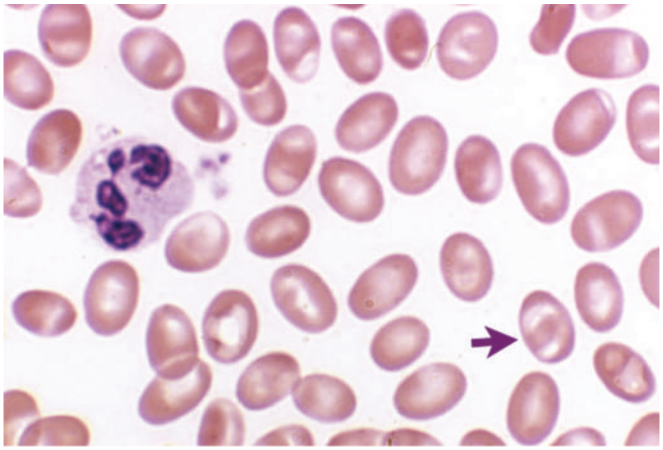

Figure 16-29 Peripheral blood morphologic findings in Southeast Asian ovalocytosis (SAO). The majority of cells are rounded elliptocytes, but some contain a transverse ridge across the central clearing, which gives them the appearance of the Greek letter theta (θ) (*arrow* denotes one example of several). Theta cells are characteristic of SAO. Elliptical stomatocytes are also evident in some patients.

The strong resistance of red cells to crenation, after several days of storage,[722] provides an additional clue to the diagnosis, as does the eosin-5′-maleimide–binding test, which shows low binding, similar to HS or HPP, because SAO band 3 does not react with the reagent.[257] SAO red cells also exhibit cryohemolysis,[723] an influx of cations and water at low temperatures leading to hemolysis, essentially identical to that seen in hereditary cryohydrocytosis (HC), another disorder of band 3 (see later section in this chapter). Thus although SAO band 3 channels cannot exchange anions, the proper function of band 3, they mistakenly transport cations. However, the most specific diagnostic test for SAO is amplification of the deleted region from the band 3 gene in genomic DNA or reticulocyte cDNA. This produces a single band in control red cells and a doublet in SAO cells, with the second band shorter by 27 bp.[710,712,723]

Curiously, many blood group antigens are poorly expressed on the surface of SAO red cells,[698] possibly because the rigid membrane inhibits their clustering and impedes agglutination. Duffy antigen is an exception and is mildly increased.[724]

SAO band 3 is a recessive mutation for distal renal tubular acidosis (dRTA). Patients who are compound heterozygotes for SAO and other band 3 mutations causing dRTA, develop the disease.[129,725,726] The reason is because sufficient heterodimers of normal and SAO band 3 reach the plasma membrane to prevent acidosis, whereas heterodimers of SAO and other dRTA band 3 molecules become trapped in the endoplasmic reticulum and lead to deficient Cl^- excretion.[142]

Resistance to Malaria

The prevalence of SAO increases with age in populations rife with malaria, suggesting that individuals with SAO have a selective advantage.[727] In vivo, there is evidence that SAO protects against all different types of malaria, particularly against heavy infections,[727,728] placental malaria during a first pregnancy,[729] and cerebral malaria in children.[730,731] For example, in infants, SAO reduces the incidence of P. vivax clinical infections by 46%.[728] On the other hand, SAO does not protect against mild malaria, asymptomatic P. falciparum malaria parasitemia, or severe malarial anemia.[728,730,732,733] In fact, SAO erythrocytes may be selectively lost during acute malaria, exacerbating the anemia.[718] In vitro, SAO red cells are resistant to invasion by malarial parasites,[734-737] though the effect is strain dependent.[737] However, population studies show no correlation between the SAO mutation and the prevalence of malaria,[703,732,733,738] with the exception of P. vivax malaria,[739] which suggests that resistance to invasion is not a factor in vivo. The fact that children with SAO are very resistant to cerebral malaria suggests that SAO may alter the endothelial adherence that underlies that complication[730,740]; however, this remains to be proved.

Membrane Rigidity

SAO red cell membranes are very rigid, 10 to 20 times more rigid than normal.[711,712,722,741] Other membrane characteristics reflect this property, including unusually high heat resistance, lack of endocytosis in response to drugs that produce dramatic endocytosis in normal cells, and strong resistance to crenation, even after several days of storage in plasma or buffered salt solutions.[722] In addition, the non-SAO band 3 molecules and other integral proteins in SAO red cells are less laterally mobile than in normal red cells, presumably more confined by interactions with the membrane skeleton.[742,743] The mechanism of the rigidity is unclear. One suggestion is that conformational changes of the cytoplasmic domain of SAO band 3 preclude lateral movement (extension) of the skeletal network during deformation.[711,744] A second possibility is that SAO band 3 itself is rigid due to loss of a flexible linker at the juncture of the cytoplasmic and membrane domains, right where the SAO deletion occurs.[745] A third explanation is that SAO band 3 binds abnormally tightly to ankyrin and thus to the underlying skeleton.[700] The increased propensity of SAO band 3 to aggregate into higher oligomers may be important because the oligomers can strengthen band 3 attachment to ankyrin.[746] Fourth, the tendency of SAO band 3 to form linear arrays would also decrease its mobility within the bilayer.[747] Finally, SAO band 3 may adhere to the skeleton in a nonspecific manner, possibly due to denaturation of the membrane spanning domain,[748] which is known to be misfolded.[749] Whatever the mechanism, it is interesting that such extremely rigid red cells circulate freely and neither clog the circulation nor are removed prematurely.

STOMATOCYTOSIS, CRYOHYDROCYTOSIS, AND XEROCYTOSIS

Red cell hydration is largely determined by the intracellular concentration of monovalent cations. A net increase in Na^+ and K^+ ions causes water to enter, forming “stomatocytes” or “hydrocytes,” whereas a net loss of monovalent cations produces dehydrated red cells or “xerocytes.” In the past 45 years, numerous descriptions of congenital or familial hemolytic anemias associated with abnormal cation permeability and, in some cases, disturbed red cell hydration have been reported. These span the range from severe stomatocytosis to severe xerocytosis. They can be divided into six, somewhat overlapping and artificial clinical categories based on differences of severity, morphology, cation content, lipid and protein composition, genetics, molecular defect, and response to splenectomy: overhydrated stomatocytosis (severe), mild stomatocytosis, cryohydrocytosis, SAO, xerocytosis, and pseudohyperkalemia (Table 16-12 and Fig. 16-30). Each of these diseases is caused by defects in normal red cell membrane transport proteins, defects that pervert the normal functions of the transporters and allow Na^+ or K^+ ions abnormal passage. This is probably a general rule for most disorders of membrane permeability: that mutations cause otherwise normal channels to be distorted and malfunction. Many of the recent advances are covered in reviews published during the past few years.[750,751]

Overhydrated Hereditary Stomatocytosis

Clinical Features

Overhydrated hereditary stomatocytosis (OHSt) is the classic form of hereditary stomatocytosis (HSt) and is characterized by cation permeability and swollen, water-laden red cells. It is a very rare hemolytic anemia. Less than two dozen patients have been reported.[752-768] OHSt red cell membranes are remarkably permeable to Na^+ and K^+ ions, particularly Na^+ ions. Intracellular Na^+ is greatly increased and K^+ is decreased, but the total monovalent cation content (Na^+ plus K^+) is high, which leads to an increase in cell water and cell volume. The resulting “edematous cells” are bowl shaped in suspension, but when they deposit on slides the extra volume encroaches on the normal circular central clearing, yielding the characteristic slit shape (see Fig. 16-30, A). Even more swollen “stomatocytes” appear as large spherocytes (see Fig. 16-30, B).

The disease is inherited in an autosomal dominant manner and presents with moderately severe to severe hemolysis and anemia, soon after birth or in infancy. In most cases the disease is constant throughout life, though we have seen patients who had severe anemia in infancy that became milder with time during the first year of life. There are no reports of how often this occurs. Hemolysis is extravascular, so that jaundice, splenomegaly, and cholelithiasis are features. Anemia may be exacerbated by intercurrent infections that activate macrophages or exacerbate splenomegaly. As with all hemolytic anemias, patients may also suffer aplastic crises if infected with parvovirus B19. In addition, because hereditary stomatocytes leak potassium as well as gain sodium, patients may be mistakenly diagnosed with hyperkalemia if electrolyte measurements are delayed after blood samples are drawn.

TABLE 16-12 Features of Hereditary Stomatocytosis-Xerocytosis Syndromes

Feature (normal value)	Overhydrated Hereditary Stomatocytosis	OTHER HEREDITARY STOMATOCYTOSIS SYNDROMES			HEREDITARY XEROCYTOSIS (DEHYDRATED STOMATOCYTOSIS)	
		Mild Hereditary Stomatocytosis	Hereditary Cryohydrocytosis	Southeast Asian Ovalocytosis	Typical	Pseudohyperkalemia
Hemolysis	Severe	Mild to moderate	Mild to moderate	Mild (neonatal only)	Moderate	Mild or none
Anemia	Moderate to severe	Mild to moderate	Mild to moderate to completely compensated	Mild (neonatal only)	Mild to moderate to completely compensated	None
Blood smear	Stomatocytes; ± spherocytes	Stomatocytes and/or spherocytes	Stomatocytes, sometimes with curved or offset stoma; ± spherocytes; ± target cells	Rounded elliptocytes, some with a double central clearing and a theta (θ) shape; ± stomatocytes	Target cells; sometimes small numbers of echinocytes or stomatocytes	Target cells; few stomatocytes
MCV	Increased	Normal to increased	Normal to increased		High normal to increased	Normal to increased

MCHC, Mean corpuscular hemoglobin concentration; *MCV*, mean cell volume; *RBC*, red blood cell.

[*] Based on a relatively small number of measurements reported in the literature.

[†] Times normal. Defined as the ouabain- and bumetanide-resistant $^{86}Rb^+$ influx at 37°C, and expressed as the ratio of patient residual leak to normal residual leak (normal = 0.06 to 0.10 mmol/L RBC/hour).

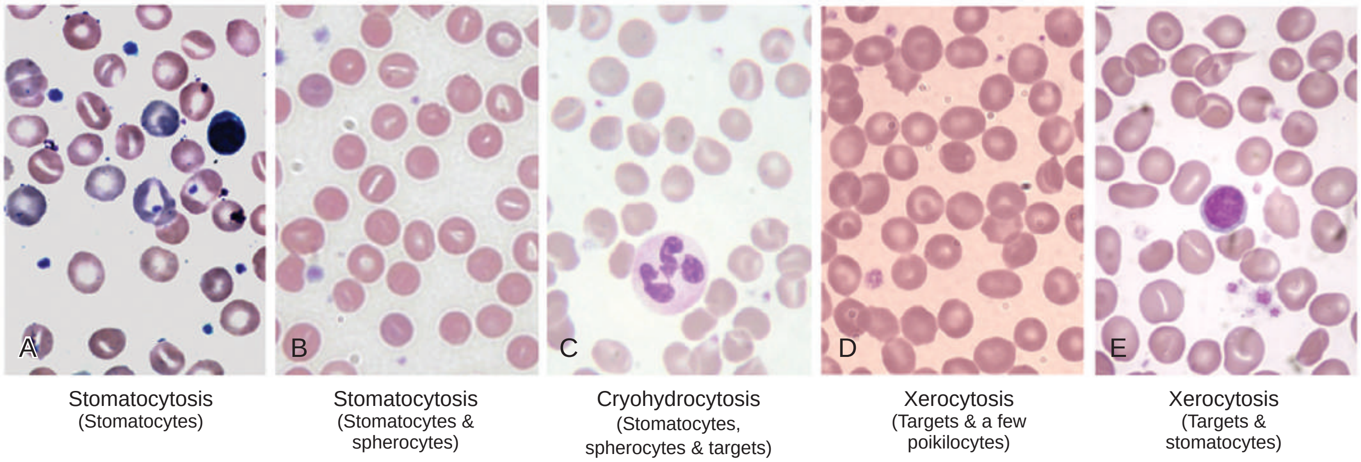

Figure 16-30 Peripheral blood morphologic findings in hereditary stomatocytosis and hereditary xerocytosis (HX). **A**, Overhydrated hereditary stomatocytosis (OHSt). Many stomatocytes and polychromatophilic erythrocytes are present. **B**, OHSt. This patient has a mixture of stomatocytes and large spherocytes. **C**, Cryohydrocytosis, type 1. A mixture of stomatocytes, spherocytes, and target cells is evident. Note that some of the stomatocytes have curvilinear slits, such as those at the upper right and upper left. **D**, HX. Typical blood smear with some target cells but mostly unimpressive morphologic characteristics. **E**, HX with some target cells and stomatocytes. *(**C**, From Bruce LJ, Robinson HC, Guizouarn H, et al: Monovalent cation leaks in human red cells caused by single amino acid substitutions in the transport domain of the band 3 chloride-bicarbonate exchanger, AE1.* Nat Genet *37:1258–1263, 2005; **E**, From Lichtman MA:* Lichtman's atlas of hematology, *New York, 2007, McGraw Hill, Figure I.C.155.)*

The diagnostic laboratory features include the unique red cell morphology (5% to 50% stomatocytes, sometimes with accompanying spherocytes), moderate to severe hemolysis, macrocytosis (95 to 150 fL), *low* MCHC (24% to 30%), and a positive osmotic fragility test. *The combination of macrocytosis and a low MCHC is virtually diagnostic for hereditary stomatocytosis,* especially when stomatocytes are present on the peripheral blood smear and the osmotic fragility test is positive. Occasionally spherocytes can dominate the smear and cause confusion, but patients with true HS *never* have macrocytosis or a low MCHC—just the opposite—so the two diseases should not be confused.

Additional studies in specialty laboratories will show a greatly elevated erythrocyte Na^+ concentration, a reduced erythrocyte K^+ concentration, an increased total Na^+ plus K^+ concentration, and an extremely high passive membrane permeability for Na^+ and K^+. The excess monovalent cations elevate cell water, which is responsible for the low MCHC.

Osmotic gradient ektacytometry, which is described in the sections on HS (see Fig. 16-18), shows a characteristic right-shifted pattern in OHSt due to increased red cell hydration (Fig. 16-31, *A*). The minimum deformability index (DI) observed in the hypotonic region of the ektacytometry curve (called O_{min}) is shifted to the right of the control region, indicating a decrease in the cell surface area–to–volume ratio. The maximum DI is normal or increased due to the increased surface area of the macrocytic cells, and the osmolality in the hyperosmolar region at which the DI reaches half its maximum value is increased because the cells are overhydrated. Osmotic gradient ektacytometry is a sensitive and specific method for diagnosing disorders of membrane permeability. Unfortunately, the equipment required is available at only a few centers.

Finally, OHSt is characterized by a marked decrease or absence of stomatin on SDS gel electrophoresis of red cell membranes or by immunostaining of erythrocytes. As will be discussed, this turns out to be a marker of the disease but is not directly implicated in its pathophysiology, which is due to mutations in the *RhAG* gene.

Pathophysiology

The major physiologic defect in hereditary stomatocytosis is a marked asymmetric increase in passive Na^+ and K^+ permeability (the amount of Na^+_{in} exceeds the amount of K^+_{out}). Permeabilities as great as 15 to 40 times normal are observed.[752,769,770] Because the influx of Na^+ predominates, stomatocytic red cells progressively gain cations and water and swell. As a result, their average density is less than normal (see Fig. 16-31, B) and the swollen stomatocytes are osmotically fragile. Unlike normal cells, aged stomatocytes are less dense and more stomatocytic than stomatocytic reticulocytes.[752]

In stomatocytosis, monovalent cation transporters are greatly stimulated by the tremendous influx of Na^+, particularly the Na^+,K^+ pump and K^+,Cl^- cotransporter.[760] The Na^+,K^+ pump attempts to extrude the Na^+ torrent, consuming much ATP in the process. If the compensatory Na^+ extrusion fails, stomatocytes would be expected to succumb to osmotic lysis, but the lack of evidence for intravascular hemolysis suggests that somehow they are recognized and eliminated by the reticuloendothelial system before they burst. Overhydrated stomatocytes are vulnerable to splenic sequestration[759] because red cell metabolism and ATP production are compromised in the stagnant, acidotic, hypoglycemic splenic cords. Analysis of metabolic intermediates in OHSt erythrocytes is compatible with increased production of ATP and glycolytic exhaustion.[771] Predictably, splenectomy has been beneficial in some patients with severe

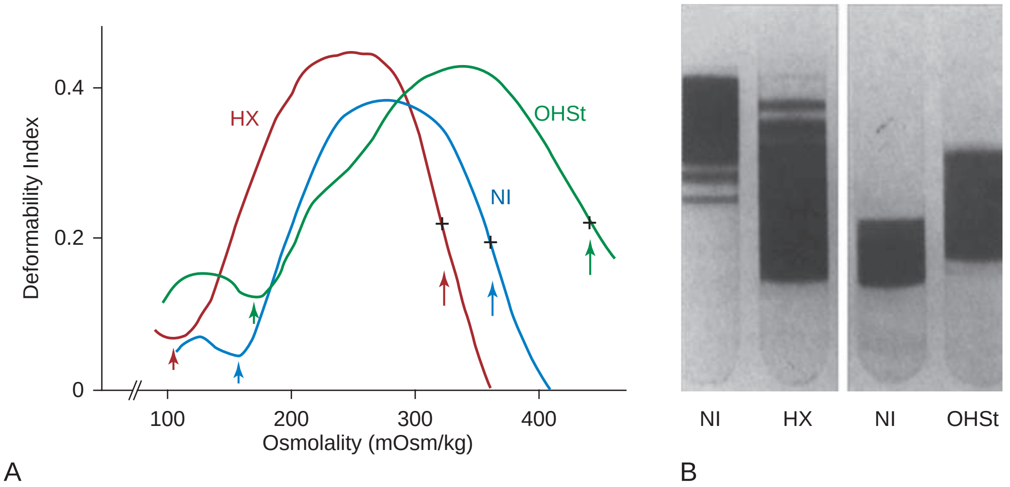

Figure 16-31 **A**, Osmotic gradient ektacytometry of hereditary xerocytosis *(HX)* and overhydrated hereditary stomatocytosis *(OHSt)* showing erythrocytes compared with normal red cells *(Nl)*. The deformability index (DI), an arbitrary measure of deformation, is plotted as a function of the osmolarity. The maximum DI is greater for both HX and OHSt red cells, indicating their greater surface areas. The minimum DI in the hypotonic region (*smaller arrows* to the *left*) is markedly shifted to the left for shrunken HX red cells, indicating their increased surface-to-volume ratio. It is shifted to the right for the swollen OHSt cells the surface-to-volume ratio of which is decreased. The osmolality in the hyperosmolar region at which the DI reaches half of its maximum value (*larger arrows* on the *right*) is a measure of the hydration state of the red cells. It is considerably decreased in the HX sample and massively increased in OHSt. **B**, Separation of xerocytes *(left)* and stomatocytes *(right)* by density on Stractan gradients. The hereditary xerocytes *(HX)* extend to higher densities (toward the bottom) than normal red cells *(Nl)*, whereas many of the overhydrated hereditary stomatocytes are lighter than normal. *(**A**, Modified from Delaunay J: The hereditary stomatocytoses: genetic disorders of the red cell membrane permeability to monovalent cations.* Semin Hematol *41:165–172, 2004; **B**, From Lande WM, Mentzer WC: Haemolytic anaemia associated with increased cation permeability.* Clin Haematol *14:89–103, 1985.)*

hemolysis[752,760,761,763,770] but not without severe risk (see later section on Treatment).

Bifunctional imidoesters, which cross-link proteins, reverse the abnormal shape and permeability of OHSt red cells and normalize their survival in the circulation.[772] The critical proteins involved have not been identified using these agents, because many red cell membrane proteins are cross-linked at the concentrations required to achieve this effect.

Stomatin. The red cell membranes of all or almost all patients with OHSt nearly lack a 31-kD protein called stomatin or band 7.2b (Fig. 16-32).[754,755,760,773-775] This small, widely distributed, integral membrane protein resides in detergent-resistant membrane lipid domains called lipid rafts, and appears to regulate ion channels.[776,777] For a time defective stomatin was believed to cause OHSt. However, the stomatin gene is entirely normal in the disease[778] and a stomatin gene knockout in mice does not cause any Na$^+$ leak in red blood cells or hemolysis.[779] Some OHSt red cells contain small amounts of stomatin; however, in most OHSt red cells stomatin is lost early in erythropoiesis.[764] Surprisingly, it turns out that stomatin normally binds to the major glucose transporter, Glut1, which also resides in lipid rafts. Stomatin switches part of the Glut1 to an L-dehydroascorbic acid transporter in red cells.[780] This only occurs in species such as humans that lack the ability to synthesize ascorbic acid. Because stomatocytic red cells consume so much ATP trying to pump out Na$^+$, it may be that the OHSt red cells that survive and circulate are those that are able to lose stomatin and retain Glut1 as a glucose channel to provide extra metabolic substrate.

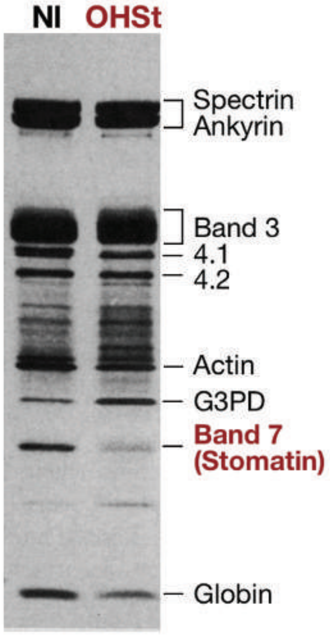

Figure 16-32 Stomatin deficiency in overhydrated hereditary stomatocytosis *(OHSt)*. Sodium dodecyl sulfate gels of normal *(Nl)* and OHSt red cell membranes show that the principal (31-kD) band in the band 7 region (stomatin) is markedly decreased. Immunoblots confirm that stomatin is nearly absent in these cells. *G3PD*, Glyceraldehyde-3-phosphate dehydrogenase. *(Modified from Rix M, Bjerrum PJ, Wieth JO, Frandsen B: Congenital stomatocytosis with hemolytic anemia—with abnormal cation permeability and defective membrane proteins.* Ugeskrift for Laeger *153:724–726, 1991.)*

How stomatin is lost is not clear. About 2% to 5% of OHSt red cells contain immunoreactive stomatin, particularly reticulocytes.[764] This suggests that stomatin is made but is lost from lipid rafts in OHSt red cells as the cells mature in the bone marrow and in the circulation. The amount of actin and tropomodulin associated with lipid rafts is markedly reduced in OHSt erythrocytes,[781] which suggests that there may be a defect in the interaction of stomatin with the membrane skeleton. Potentially that could cause stomatin to be lost in the exocytic vesicles that are released as the red cell matures into a reticulocyte and that eliminate proteins such as the transferrin receptor from normal mature red cells. On the other hand, in cultured erythroid cells from OHSt patients, stomatin is confined to multivesicular complexes and the nucleus and is not seen on the plasma membrane,[782] which suggests that stomatin deficiency may result from a trafficking defect. Stomatin is also deficient in red cells from patients with type 2 cryohydrocytosis (see below) and in dogs whose red cells have a genetic polymorphism that downregulates the Na^+,K^+ pump.[783]

Defect in RhAG in Overhydrated Hereditary Stomatocytosis Erythrocytes. All of the patients with classic OHSt studied so far have mutations in the RhAG protein (Rh-associated glycoprotein; gene name *RHAG*)[765,767] (Fig. 16-33, *A*). RhAG associates with the RhD and RhCE proteins that carry the Rh antigens to form the Rh complex. This complex resides in a larger membrane protein complex that includes the red cell adhesion proteins CD47 and LW, band 3 (the Cl^-–HCO_3^- exchange channel), and glycophorin B, which serves as a chaperone to bring RhAG to the membrane.[784] The complex binds to ankyrin.[785,786] RhAG has the typical structure of a protein channel, with 12 transmembrane helices. It functions as an ammonium ion channel[787-789] and/or a gas (NH_3, CO_2) channel[790,791] in addition to helping display Rh blood groups. So far, all OHSt patients have mutations in one of just two conserved amino acids in the second transmembrane helix, Ile61Arg or Ser65Phe, and all but one of those have the Ser65Phe mutation. The extremely limited spectrum of causative mutations may explain the rarity of this disease. The two mutations above impinge on the presumptive ammonium channel and presumably disrupt the channel structure (see Fig. 16-33, *B*). In fact, the mutant RhAG proteins induce large cation leaks when introduced into oocytes.[767]

Treatment: Splenectomy Is Dangerous

The swollen, water-laden stomatocytes have trouble negotiating the spleen, where the acidotic and hypoglycemic environment impairs their ability to synthesize ATP and expel the inward torrent of Na^+ and water via the Na^+,K^+-ATPase pump.[759] As a consequence, the spleen is a graveyard for stomatocytes and splenectomy is an effective though incomplete therapy (i.e., the anemia is only partially relieved).[752,753,760,761,770]

However, physicians who care for patients with either OHSt or hereditary xerocytosis (HX, to be discussed) agree that there is a high risk of thromboembolic complications following splenectomy, so much so that the operation is contraindicated in these diseases in all but extreme situations. Unfortunately, the data backing up this prohibition are not very extensive. The recommendation flows primarily from a single study, a retrospective compilation of case reports of nine splenectomized adults collected by Stewart and colleagues in 1996.[277] All the patients were labeled as having "hereditary stomatocytosis," but some had OHSt and others had HX. Both groups suffered from serious thrombotic complications, sometimes recurrent over years, including deep venous thrombosis, pulmonary embolism, superficial thrombophlebitis, portal vein thrombosis, intracardiac mural thrombosis, arterial thrombosis, and pulmonary hypertension. Four of the nine patients died, and the author is aware of another splenectomized adult patient

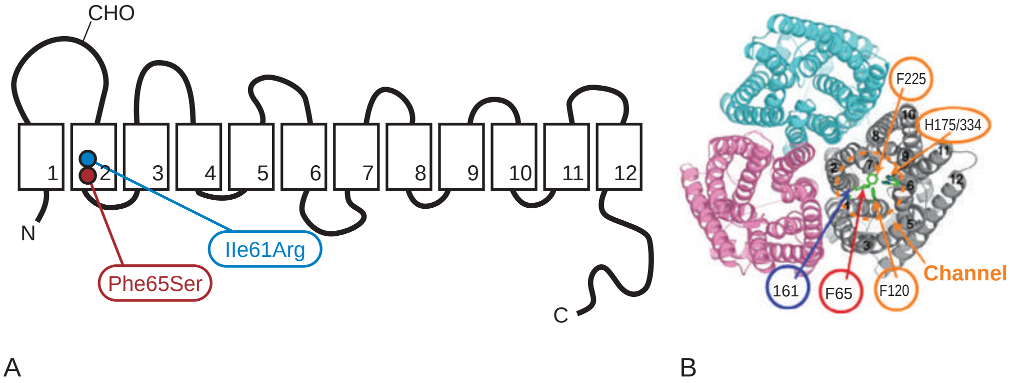

Figure 16-33 **A**, Model of Rh-associated glycoprotein (RhAG) showing the mutations that cause overhydrated hereditary stomatocytosis (OHSt). The extracellular space is on top. Almost all patients have the Phe65Ser defect. **B**, Structural model of an RhAG trimeric complex looking from the outside of the cell. Histidines 175 and 334 and phenylalanines 120 and 225 (marked in orange) are believed to lie within a channel that the RhAG protein uses to transport NH_4^+ ions or NH_3 or CO_2 gas molecules. Note that the amino acids mutated in OHSt (marked in red and blue) lie within this channel, where they could potentially alter its permeability and induce the massive influx of Na^+ ions that causes the disease. *CHO* indicates the location of side chain carbohydrate on RhAG. *(**B**, Modified from Bruce LJ, Guizouarn H, Burton NM, et al: The monovalent cation leak in overhydrated stomatocytic red blood cells results from amino acid substitutions in the Rh-associated glycoprotein.* Blood *113:1350–1357, 2009.)*

with hereditary stomatocytosis[752] who died of thromboembolic complications years after the operation. No such complications were observed in six affected but unsplenectomized adults. There have been six additional reports of individuals with OHSt or HX who developed severe thrombotic complications in the 18 years since this initial paper became available.[792-795] Given the retrospective, incomplete, and anecdotal nature of all these reports; the lack of paired unsplenectomized controls; and other inherent flaws, it is impossible to estimate the precise risk of splenectomy in these two diseases, but it is apparent that it is high and that splenectomy, which is only partially effective in OHSt and ineffective in HX, should be avoided.

We do not clearly understand why thrombotic complications are so much higher after splenectomy in these diseases than in similar conditions such as HS. Stomatocytes have about fourfold more phosphatidylserine (PS) on their surfaces than control cells.[796] PS exposed on the outer surface of cells is highly thrombogenic.[797,798] Such cells are cleared by macrophages, which have PS receptors on their surfaces.[799-801] This function would presumably be impaired after splenectomy. In vitro, erythrocytes from two splenectomized individuals with hereditary stomatocytosis show mildly increased adherence to endothelial monolayers.[796,802] This might also contribute to a hypercoagulable state.

Fortunately, in most cases, patients with OHSt have a tolerable degree of hemolysis and anemia and do not require any dramatic interventions, or at most occasional transfusions for intermittent hemolytic or aplastic crises. In occasional patients the anemia is severe enough (usually a hemoglobin value of ≤5 to 7 g/dL) to slow growth, greatly decrease normal energy, or cause congestive heart failure, in which case the physician is faced with the unpalatable choice of chronic transfusions coupled with iron chelation therapy, splenectomy followed by life-long anticoagulation, or bone marrow transplantation. The propensity for iron overload in this disease further complicates the options for chronic transfusion therapy and bone marrow transplantation. There is insufficient information about the relative risks of these unappealing therapeutic options in OHSt patients to offer rational advice on how to choose among them.

We recommend that patients who have already been splenectomized be placed on chronic coumadin therapy and that they avoid contraceptives and, if possible, pregnancy.

Like all severe hemolytic anemia patients, patients with OHSt should receive regular folic acid supplementation (1 mg/day), and, because iron overload is common in this disorder, even in the absence of transfusions, iron stores should be monitored.

Hereditary Xerocytosis (Dehydrated Hereditary Stomatocytosis, High Phosphatidylcholine Hemolytic Anemia)

Hereditary xerocytosis (HX) is the most common red cell cation permeability disorder. It is inherited as an autosomal dominant disorder. HX also goes by the name of dehydrated hereditary stomatocytosis. This is a very unfortunate name because the blood smears of most patients show few, if any, stomatocytes and the term leads to confusion with OHSt, which is an entirely different disease. In fact, most patient blood smears are surprisingly normal (see Fig. 30, D), with a few target cells, some irregular spiculated cells, and rare stomatocytes.

Clinical Features

HX is characterized by a mild increase in potassium permeability that is sufficient to lead to the gradual loss of red cell K^+ and water, and to red cell dehydration, stiffness, and hemolysis. Multiple families have been described.[200,228,229,803,804,805-814,815-830] The disease is estimated to have a prevalence of 1 in 50,000; however, because blood smears are unimpressive and the anemia is often fully compensated (i.e., hemoglobin levels are normal), and because red cell electrolyte measurements are hard to obtain, it is likely that many, and probably most, patients go undiagnosed.

Patients with HX may present at any age for evaluation of reticulocytosis, stomatocytosis, pseudohyperkalemia, jaundice, gallstones, or splenomegaly. Hemoglobin and hematocrit values are often normal despite evidence for mild to moderate hemolysis, suggesting that *patients are physiologically more anemic than the numbers suggest*. There is some evidence that the viscous, dehydrated red cells do not traverse the kidney well, leading to less oxygen reaching the juxtaglomerular apparatus, which would stimulate more erythropoietin production and lead to a higher hemoglobin level than would be expected for the degree of hemolysis.

Red cell 2,3-DPG concentrations are moderately decreased in HX,[200,803,813,814,832] just as they are in hereditary stomatocytosis. The reasons are unknown. Because loss of the polyvalent DPG is compensated for by an influx of monovalent chloride ions and water, patients with xerocytosis and unusually low DPG levels have fewer dehydrated red cells than expected for the degree of cation loss and in rare cases have no dehydrated cells at all.[832] Patients with low DPG levels also have increased whole-blood oxygen affinity.[823,832] This may also contribute to their relative polycythemia. The bottom line is HX patients are probably more anemic functionally than their hemoglobin levels suggest, a point clinicians need to consider.

HX red cells have a reduced K^+ concentration and reduced total monovalent cations (Na^+ plus K^+) (see Table 16-12). *Red cell morphology is usually unimpressive.* There are typically a few target cells, occasionally a modest number, and sometimes a few echinocytes, a few stomatocytes (<5%), or some dense, contracted, irregular cells (see Fig. 16-30, *D*). Occasionally, stomatocytes are more apparent (see Fig. 16-30, *E*), especially in the very rare patients with homozygous HX.[811] In addition, in the most severely affected patients, particularly after splenectomy, blood smears may display some contracted and spiculated red cells and cells in which the hemoglobin appears to be aggregated in one portion of the cell.[803]

The MCV ranges from high normal to macrocytic and the MCHC is typically elevated. The high MCV is partially an artifact of cellular stiffness. In Coulter-type electronic counters, the measurement of MCV depends on the cell shape. Xerocytes do not deform to the same degree as normal cells, which causes the electronically measured MCV to be about 10% too high[831] and leads to a corresponding increase in the hematocrit, which is calculated using the MCV. However, the MCV of HX red cells is also high in cell counters that measure MCV by light scattering, so it appears the cells really are macrocytic. Because the red cells are dehydrated, the osmotic fragility curve is always shifted toward osmotic resistance, though the effect can sometimes be subtle.[811] *The combination of macrocytic cells that are dehydrated (resistant osmotic fragility and high MCHC) should strongly suggest the diagnosis of HX*.

Nonimmune Hydrops. A constellation of clinical findings, including anemia, jaundice, pseudohyperkalemia, fetal or perinatal edema or ascites, and even hydrops fetalis, has been described in the fetal and newborn period in HX patients.[805,806,825,826,833] Different combinations of these features occur in different patients. Only a subset of infants develop intrauterine or perinatal fluid effusions. The effusions vary remarkably in severity, regress spontaneously, either in utero or soon after birth (a few months at most), and do not reappear. The cause of this complication and how it relates to the red blood cell permeability defect is a complete mystery. It does not seem to be related to anemia or hypoalbuminemia. Although treatments such intrauterine transfusions and albumin infusions have been employed, the efficacy of these interventions is difficult to assess due to the spontaneous resolution of symptoms.[821,826,833]

Iron Overload. The clinical course of HX is also remarkable for iron overload in the absence of transfusions, even more so in patients who are heterozygous for a hemochromatosis gene.[828] The serum iron, serum ferritin, and iron saturation values are usually high in affected adults and often require treatment. The degree of iron overload is greater than that of other hemolytic anemias, except for those characterized by ineffective erythropoiesis. The underlying cause is not understood.

Pathophysiology

Physiologically, the major red cell abnormality is a change in the relative permeability of the membrane to potassium. Efflux of K^+ is increased twofold to fourfold and approximates or slightly exceeds Na^+ influx.[750,803] Na^+,K^+ pump activity is increased appropriately for the slightly elevated Na^+ content, but the pump cannot compensate for K^+ losses in excess of Na^+ gain, because the pump expels three Na^+ ions for every two K^+ ions it returns,[834,835] which is the normal ratio of the Na^+_{in} and K^+_{out} leaks. As a consequence, the K^+ permeability defect, though modest, causes HX red cells to gradually become cation depleted and dehydrated.

Defect in the Piezo1 Mechanotransducer Channel. The defective gene was originally mapped to chromosome 16q23-q24,[805,836,837] but that was then revised to the adjacent telomeric segment (16q24.2-qter),[830] which led to identification of Piezo1 (gene name *FAM38A*) as the responsible protein.[227] Missense mutations in conserved amino acids near the middle and tail end of the protein were found in 24 families (Fig. 16-34).[227,228,229,838] These include families with the features of pseudohyperkalemia and perinatal edema as well hemolysis and red cell dehydration. A total of 14 mutations were identified. One family (kindred Bicêtre)[228] carried two Piezo1 mutations (*G782S* and *R808Q*). One common mutation that added two amino acids to the sequence (*E2496ELE*) was found in 8 of 11 French families but not in families from other countries, suggesting a founder effect.[229] Two other mutations were found in two (*T2127M*) and four (*R2456H*) apparently unrelated families.

There are two Piezo proteins (Piezo1 and Piezo2). They are very large, widely distributed proteins and form huge multimeric cation channels, with 120 to 160 transmembrane segments, which are triggered by mechanical distortion of the membrane[225,226] (reviewed[859]). Piezo proteins are involved in pain sensing[225] and perhaps in other mechanical sensations such as hearing and touch. The presence of Piezo1 in the red blood cell membrane suggests the proteins may also be involved in homeostatic adjustments to changes in volume, responding to membrane stretch. In fact, the HX mutations lengthen the time it takes to activate the Piezo1 channel after membrane deformation and slow the time it takes to deactivate it.[840] How these changes in channel function lead to K^+ loss and cell dehydration in hereditary xerocytes is not yet clear. Perhaps the lost K^+ ions simply flow out through the mutant Piezo1 channel. Alternatively, K^+ loss may be a secondary consequence of excess Ca^{2+} entry through the mutant channel. It is known that Ca^{2+} enters normal red cells when they are deformed. It is likely that this occurs through Piezo1 and triggers Ca^{2+}-stimulated K^+ loss via the Gárdos channel. It is a mystery why defects in the widely distributed, evolutionarily conserved Piezo1 channel do not have more widespread pathologic effects in HX, especially in homozygotes,[811] which some of the sequenced patients were.[227] Perhaps red cells have only Piezo1 whereas other cells have both Piezo1 and Piezo2, providing redundancy.

Red cells from some HX patients have an increased proportion of the phospholipid phosphatidylcholine in their membranes (12 to 20 fmol/cell; normal range, 10 to 12 fmol/cell), and their disorder was initially given the name *high phosphatidylcholine hemolytic anemia*.[808,812,816,819,820,822] It is not clear if this is true of all HX patients or demarcates a subset of the disease, but there seems to be little to differentiate the two diseases.[820] Early studies suggested the excess phosphatidylcholine was due to diminished transfer of phosphatidylcholine fatty acids to phosphatidylethanolamine,[816] a pathway that is normally stimulated by cellular dehydration. It is not clear why this pathway is inhibited in HX or how it relates to the underlying membrane leakiness and hemolysis.

Xerocytes are also shear sensitive[815] and are exceptionally prone to membrane fragmentation in response to metabolic stress.[200] It is interesting to speculate that this

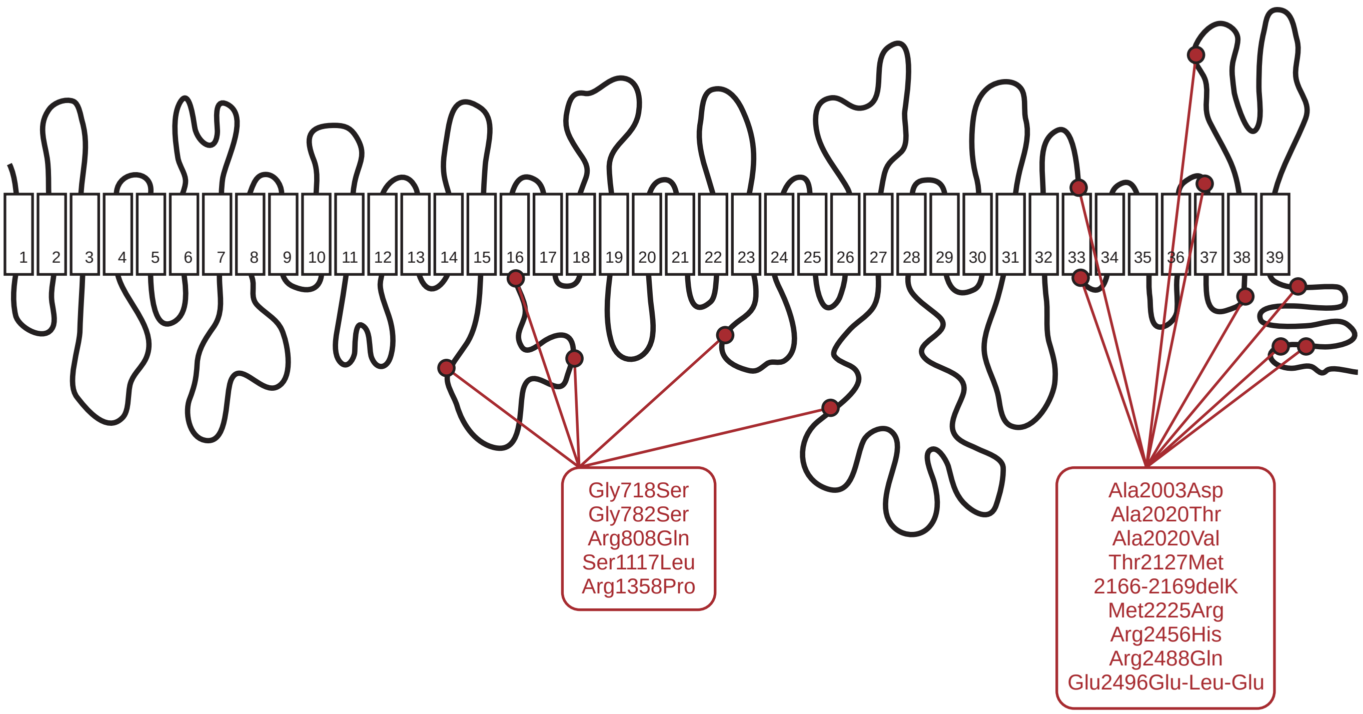

Figure 16-34 Model of Piezo1 (gene name FAM38A), a very large mechanotransducer protein involved in red cell volume regulation, showing mutations that cause hereditary xerocytosis. The extracellular space is on top. The mutations are grouped in the middle and C-terminus of the protein. One mutation (Glu2946Glu-Leu-Leu) was found in 8 of 11 French families, and two others (T2127M) and (Arg2456His) occurred in two and four unrelated families, respectively. *(From Zarychanski R, Schulz VP, Houston BL, et al: Mutations in the mechanotransduction protein PIEZO1 are associated with hereditary xerocytosis.* Blood *120:1908–1915, 2012; Andolfo I, Alper SL, De Franceschi L, et al: Multiple clinical forms of dehydrated hereditary stomatocytosis arise from mutations in PIEZO1.* Blood *121:3925–3935, 2013; and Albuisson J, Murthy SE, Bandell M, et al: Dehydrated hereditary stomatocytosis linked to gain-of-function mutations in mechanically activated PIEZO1 ion channels.* Nat Commun *4:1884, 2013.)*

is somehow related to the defect in Piezo1, a channel that responds to membrane distortions such as shear. However, similar shear sensitivity can be induced in normal red cells by dehydrating them[815] and is also observed in other conditions, such as sickle cell disease,[841] where red cell dehydration occurs. One consequence is that strenuous exercise can exacerbate hemolysis in HX.[815]

Treatment

As discussed in the previous section, there is considerable evidence that life-threatening thromboembolic complications are frequent after splenectomy in HX as well as in OHSt.[277] Because severe hemolysis and anemia requiring treatment are rare in HX, and because splenectomy is ineffective in quelling hemolysis, HX patients should never be splenectomized. Unfortunately many patients are, having been mistakenly diagnosed as having HS. In such instances we recommend life-long anticoagulation, though it is uncertain if this is always protective.

As noted, iron overload is a common though poorly understood complication of HX, more so than in the other disorders of cation permeability.[277,828] In some patients the problem is severe and tissue iron deposition is great enough to damage the liver and other organs.[828] For this reason, *all patients with HX should have their iron status regularly monitored,* and, if necessary, they should be treated with deferasirox or other iron chelators. The treatment of iron overload is discussed in more detail in Chapter 21.

Familial Pseudohyperkalemia

A small number of families are reported with a dominantly inherited disorder characterized by erythrocyte K^+ loss, through a passive K^+ leak across the red cell membrane, which occurs when blood is allowed to stand for a few hours at room temperature or below.[804,842-848] Electrolyte analyses may falsely suggest that affected individuals are hyperkalemic. The leak is insignificant at body temperatures, so familial pseudohyperkalemia (FP) is symptomless and affected patients experience little or no hemolysis and no anemia. Osmotic fragility and osmotic gradient ektacytometry are normal. The MCV is mildly elevated in some cases,[804] and red cell Na^+ and K^+ are mildly increased and decreased, respectively. In particular the patients have a normal electrocardiogram and do not have evidence of acidosis, renal failure, Addison disease, or hypertension. If they do have hypertension, they do not have hyporeninemic hypoaldosteronism (Gordon syndrome), in which hyperkalemia is genuine. The key point clinically is to be sure these patients do not receive hyperkalemic therapy, which could cause severe hypokalemia.

The most common form of FP is apparently a mild form of HX because it maps to the same locus as HX on chromosome 16.[805,836,849] The temperature dependence of the cation leak in FP varies considerably, which may simply reflect different alleles in the same transporter or may reflect defects in different genes.

A second form of FP maps to chromosome 2 (2q35)[850] and is associated with mutations in the ABCB6 transporter.[851] ABCB6 is one of the ATP-binding cassette proteins and functions as a mitochondrial porphyrin transporter, but it is also expressed in the red cell membrane and carries the Lan (Langereis) blood group.

In addition, patients with hereditary spherocytosis, stomatocytosis, xerocytosis, or cryohydrocytosis all have red cells that leak K^+ and may also show pseudohyperkalemia if blood is drawn and is not analyzed quickly.

Other Hereditary Stomatocytosis Syndromes

Between the extremes of OHSt and HX there are a series of disorders characterized by mild to moderate hemolysis and anemia; stomatocytosis or spherocytosis or both; and abnormal cation permeability. All but one of these conditions is caused by missense mutations in band 3, the anion exchanger, which alter its permeability. For the purposes of this chapter these disorders are sorted into categories, but, with the exception of hereditary cryohydrocytosis (HC), type 2, which has a different genetic basis, they are overlapping variations on a phenotypic theme.

Mild Hereditary Stomatocytosis

Clinical Features. Some patients with hereditary stomatocytosis have disease similar to the classic overhydrated variant described above, except that hemolysis and anemia are milder (see Table 16-12).[769,774,852,853-857] The degree of stomatocytosis may be less; in one case no stomatocytes were evident on the peripheral blood smear.[854] The osmotic fragility test may also be normal or may show the expected fragile red cells. One family also had evidence of dyserythropoiesis.[855] Red cell stomatin concentrations are normal or only mildly decreased. The two genetically tested patients had mutations in band 3.[854,855] Some patients with severe permeability defects have had little or no hemolysis.[769] In addition, studies of 44 Japanese patients with a stomatin-sufficient form of stomatocytosis showed that the proportion of stomatocytes and the degree of Na^+ influx did not correlate with each other, and neither correlated with the amount of hemolysis or anemia.[774] This suggests that factors other than the Na^+ leak influence the demise of the stomatocyte. Splenectomy has not been clearly beneficial, and at least one patient died with pulmonary hypertension some years after splenectomy.[857]

Defect in Band 3. Four defects in the membrane domain of band 3 (gene name *SLC4A1*) have been identified in five families with the mild variant of hereditary stomatocytosis (Fig. 16-35)[854,856,858] and in a family with stomatocytosis and dyserythropoiesis.[855] Band 3 is the major erythrocyte membrane protein and is the anion channel responsible for shuttling chloride and bicarbonate ions across the membrane, which aids in the transport of CO_2 from tissues to the lungs. Quantitative deficiency of band 3 causes hereditary spherocytosis, not stomatocytosis. In these stomatocytosis patients, normal amounts of band 3 are made but the defects abolish anion exchange function.[854,858] Two of the mutations convert the putative anion channel[859] to a Na^+,K^+ conductance pathway (Leu687Pro and Gly796Arg).[854,860] The third mutation (Arg730Cys) does not.[854] Perhaps in that case the mutant band 3 perturbs a neighboring channel.

Hereditary Cryohydrocytosis

Hereditary Cryohydrocytosis Type 1: Normal Stomatin and Defect in Band 3. Hereditary cryohydrocytosis, type 1 (HC-1)[766,767,853,858,861-865] is a rare autosomal dominant disorder that is milder than the classic overhydrated form of hereditary stomatocytosis (OHSt) and similar clinically to the mild form of hereditary stomatocytosis described in the preceding paragraph. It differs in having a cold-sensitive monovalent cation leak (see Table 16-12). Na^+ and K^+ concentrations and permeabilities are less abnormal at physiologic temperatures in HC-1 than in OHSt, but instead of declining with temperature, as in OHSt, cation permeability increases below 20°C, exceeding the ability of the red cell to compensate. As a consequence, red cells from patients with HC-1, collected in EDTA or heparin, swell and partially hemolyze when stored in the refrigerator overnight.[853,861,862,864] This is a requirement for the diagnosis of HC and is its signature feature. This temperature sensitivity means that red cell measurements in these patients must be completed before a blood sample is allowed to cool.

Patients with HC-1 have mild to moderate hemolysis, with or without anemia.[853,861,862] Their red cells are mildly macrocytic and slightly osmotically fragile. They tend to be stomatocytic (see Fig. 16-30, C). The author and others[853] have observed a tendency for the slit of the "stoma" to be curved and eccentrically placed, a finding that the authors have not observed in other conditions. Several such cells are seen at the top left and top right of Figure 16-30, C. However, this characteristic is not always present. Spherocytes may also be seen. The MCHC is variable in cryohydrocytosis and is not consistently low as in severe overhydrated stomatocytosis, and the MCV is also not always macrocytic. Unlike HC-2 (see below), HC-1 erythrocytes have normal concentrations of stomatin.

Patients with HC-1 may present at any age with macrocytosis, anemia, reticulocytosis, intermittent jaundice, gallstones, pseudohyperkalemia, a palpable spleen tip, or stomatocytosis, or the diagnosis may be made because cold hemolysis is noted by an astute laboratory technician.

The primary molecular lesions in HC-1 occur in the intramembrane domain of the band 3 (or AE1) anion exchanger encoded by the *SLC4A1* gene (see Fig. 16-35).[767,858] The mutations occur in a region toward the C-terminal end of band 3, a region that is thought to form part of the anion channel. Anion exchange is decreased in the mutants and cation permeability is increased, suggesting that the mutations convert the anion exchanger into a leaky cation channel. At physiologic temperatures the cation leak and hemolysis are modest, but at temperatures below 20°C the leak is exacerbated, leading to Na^+

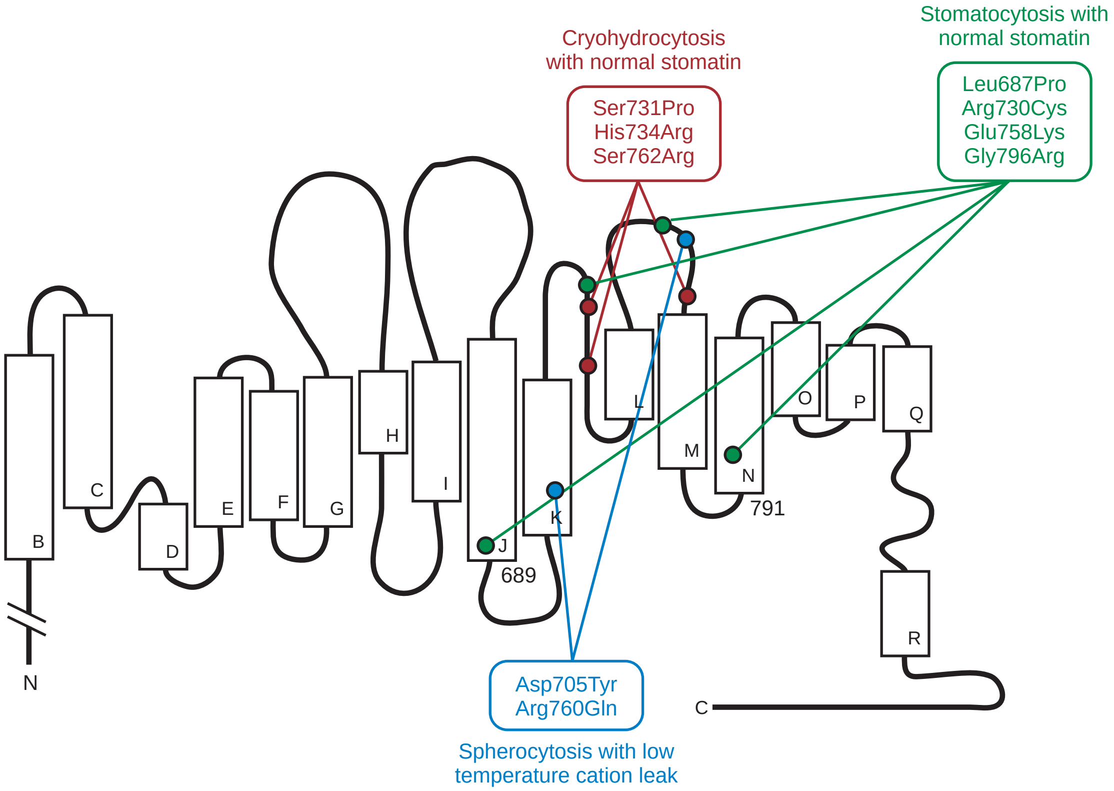

Figure 16-35 Model[859] of band 3 (also called AE1 and SLC4A1), the red cell anion exchanger and the major red cell integral membrane protein, based on the ClC chloride channel (see Fig. 15-7). The mutations shown cause mild hereditary stomatocytosis *(green circles)*, type 1 hereditary cryohydrocytosis *(red circles)*, and a form of hereditary spherocytosis (HS) with a low-temperature cation leak that is better classified as a subset of cryohydrocytosis *(blue circles)*. The extracellular space is on top. Note that all the mutations lie within a segment of the membrane domain between helices J and N. Presumably this portion of the protein must form part of the anion exchange channel. The mutations illustrate the range of phenotypes that can be produced by mutations within the same protein; mutations that presumably all function by altering the permeability of the protein channel in slightly different ways. The Gly796Arg mutation is also associated with dyserythropoiesis.

and water influx and osmotic lysis.[858] Why some band 3 mutations are cold sensitive and others are not is a mystery. Presumably the conformational changes produced by the temperature-sensitive mutations worsen at low temperatures. The sensitivity to low temperatures suggests critical hydrophobic bonds may be involved because hydrophobic bonds become weaker as temperatures fall. There is also evidence that the primary defect in band 3 may indirectly activate other cation channels at low temperatures under certain conditions.[865]

Hematologic improvement has not been reported after splenectomy in HC, but very few patients with this relatively mild disorder have had their spleens removed. Thrombotic complications have also not been reported, but it appears there is little to be gained from splenectomy and it is impossible to be certain that the risk is low.

Hereditary Spherocytosis with a Low-Temperature Cation Leak and Defect in Band 3. On the peripheral blood smears of some patients, spherocytes predominate or are the sole red cells seen.[858,865] These patients are essentially indistinguishable from those with HS except that they have a low-temperature cation leak (LTL) that mimics that seen in HC-1 and their MCHC tends to be lower than in typical HS.[858] Typical HS patients have a small cation leak, but it is much less than in HS-LTL and it does not show any augmentation at low temperatures.[858]

All of the reported patients have missense mutations in band 3 that are very similar to those observed in mild stomatocytosis and cryohydrocytosis (see Fig. 16-35) and that presumably pervert the function of band 3. In typical HS, on the other hand, when band 3 is involved the mutations cause deficiency but not dysfunction of the protein. Perhaps in these patients the missense mutations destabilize band 3, leading to band 3 deficiency and an HS phenotype, yet allow enough of the leaky band 3 to reach the surface to alter Na^+ permeability. In a small survey, 2 of 16 HS pedigrees had the HS-LTL phenotype.[858] It seems doubtful that HS-LTL is actually so prevalent, because band 3 mutations of all types account for only about 25% of HS cases,[57] but the phenotype may not be rare.

The reported families had mild to moderate hemolysis and anemia and benefited greatly from splenectomy. However, one of the four splenectomized members of one kindred had a deep vein thrombosis years after his splenectomy and then developed pulmonary hypertension presumed to be of thrombotic origin.[858] He also carried the factor V Leiden polymorphism, but even so, it seems prudent to avoid splenectomy in this subset of HS/HC-1 patients until more data are available. Findings in these patients support the argument that a test for cryohemolysis should be included in the workup of patients with HS, at least those for whom splenectomy is being considered.

Hereditary Cryohydrocytosis Type 2: Stomatin Deficiency and Defect in Glut1. Type 2 hereditary cryohydrocytosis (HC-2) has been observed in only two families so far and is associated with loss of red cell stomatin, which occurs during reticulocyte maturation. The hematologic picture resembles that of HC-1, except that peripheral red cell morphologic findings are nearly normal, with just a few echinocytes and stomatocytes.[766,866] However, the patients also have cataracts and a variety of neurologic features, including seizures, mental retardation, spastic rigidity, dyskinesias, and ataxia.[755,766] The older patients also had massive hepatosplenomegaly. Pseudohyperkalemia is reported.[866] HC-2 red cells are macrocytic and osmotically resistant.

HC-2 is caused by mutations in glucose transporter 1, or Glut1 (gene name *SLC2A1*) (Fig. 16-36),[866] which, as noted earlier, binds stomatin and is converted to an L-dehydroascorbate transporter in human red cells and other tissues. The mutations block glucose transport and induce a cation leak. The block in glucose transport causes the characteristic neurologic symptoms (seizures, mental retardation, and movement disorders). The hemolysis and cataracts appear to be due to the altered cation permeability of the mutant channel. Many (>60) patients have been described with a similar neurologic phenotype who are heterozygous for defects in Glut1 (so-called *Glut1 deficiency disorder*),[867] but these patients do not have hemolysis or cataracts and their Glut1 mutations do not increase Na^+ or K^+ permeability. They just block glucose transport. Only three HC-2 families with Glut1 mutations have been identified so far, and two have the same mutation (Ile435del). Although the hemolysis is so mild that some HC-2 patients may be misclassified as having simple Glut1 deficiency disorder, it seems more likely that, like OHSt, the disease is rare because only a few mutations allow Na^+ and K^+ to leak through the glucose channel, causing hemolysis. A fourth family is known whose members are heterozygous for a 4–amino acid in-frame deletion of Glut1 that increases the permeability of Ca^{2+} as well as Na^+ and K^+ (see Fig. 16-36).[868] The affected members also have a mild hemolytic anemia, but their red blood cells are dehydrated due to Ca^{2+} stimulation of K^+ egress (the so-called *Gárdos channel*), and are prominently echinocytic instead of stomatocytic or normal appearing.

In patients with HC-2, seizures and other neurologic complications dominate the clinical picture. The neurologic symptoms are believed to be due to inadequate glucose transport into the brain.[866] In other patients with defects in Glut1 who lack the hemolytic component, there is evidence that the seizures improve when the patient is placed on a ketogenic diet[869]; this finding includes one child with HC-2 disease.[866] Hemolysis and anemia are mild to moderate in HC-2 and do not require treatment.

Southeast Asian Ovalocytosis

Southeast Asian ovalocytosis (SAO) was discussed earlier in the chapter as a subtype of HE, but it is mentioned here because recent studies show that SAO red cells have the cation permeability properties of cryohydrocytes, including the cold sensitivity.[723] The primary defect is a deletion of nine amino acids (400 to 408) at the beginning

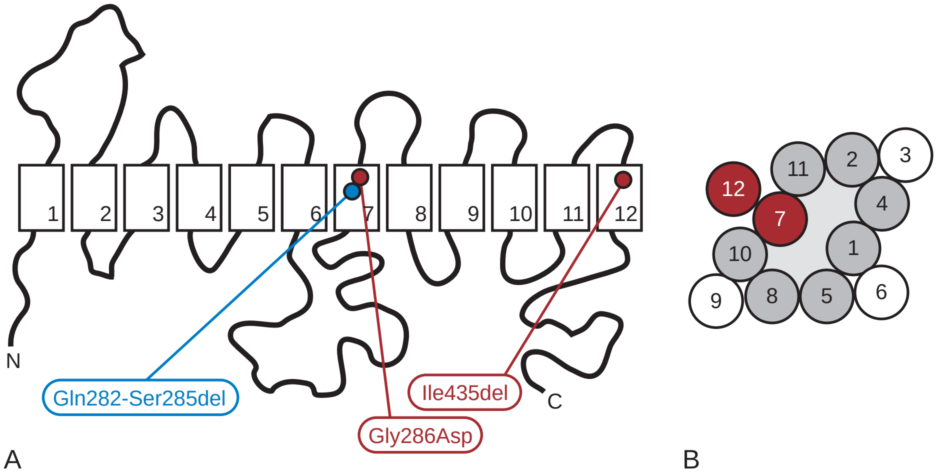

Figure 16-36 **A**, Model of glucose transporter 1 (Glut1) showing the mutations that have been identified in kindreds with hemolytic anemia, neurologic deficits, and either type 2 cryohydrocytosis *(red circles)* or hereditary echinocytosis *(blue circle)*. Two of the three reported HC2 kindreds have the Ile435 deletion. Many other defects in Glut1 are known that cause neurologic disease alone, without hemolysis or anemia. **B**, Model of Glut1 showing a proposed arrangement of the various transmembrane helices. The defects in helix 7 impinge directly on the putative glucose transport pathway. The defect in the adjacent helix 12 is believed to produce large conformational changes that distort the channel indirectly. *(**A**, Modified from Flatt JF, Guizouarn H, Burton NM, et al: Stomatin-deficient cryohydrocytosis results from mutations in SLC2A1: a novel form of GLUT1 deficiency syndrome.* Blood *118:5267–5277, 2011;* ***B****, Modified from Weber YG, Storch A, Wuttke TV, et al: GLUT1 mutations are a cause of paroxysmal exertion-induced dyskinesias and induce hemolytic anemia by a cation leak.* J Clin Invest *118:2157–2168, 2008.)*

of the first transmembrane domain of band 3,[710] which causes the protein to misfold. However, the mutant band 3 can still traffic to the membrane, where it mistakenly conducts cations.[723]

Stomatocytosis with a Defect in Palmitoylation

Two elderly brothers in a Polish family have recently been described with a mild macrocytic, stomatocytic hemolytic anemia (hemoglobin 11 to 13 g/dL, MCV 101 to 104 fL, normal MCHC, and reticulocytosis 7% to 8%), with normal erythrocyte Na^+ and K^+ concentrations, normal stomatin, some basophilic stippling, indirect hyperbilirubinemia, and a positive osmotic fragility test.[870] Biochemical studies revealed a marked defect in the palmitoylation of red cell membrane proteins, especially p55, the major palmitoylated protein, due to a deficiency of DHHC17, the sole acyltransferase in the mature red cell. The numbers of lipid rafts (see Chapter 15) are also markedly diminished. It is unclear how these defects relate to the clinical phenotype.

Classification Based on the Temperature Dependence of Cation Leaks

Gordon Stewart and his colleagues have established a classification system of the disorders of red cell membrane cation permeability based on the effects of temperature on membrane cation leak.[805,852,862,871] The membrane leak is measured by the residual influx of $^{86}Rb^+$ (a radioactive substitute for K^+) across the red cell membrane in the presence of ouabain (to inhibit the Na^+,K^+-ATPase pump) and bumetanide (to inhibit the $Na^+,K^+,2Cl^-$ cotransporter). This measurement is often taken as a measure of the passive permeability of monovalent cations, although it does not exclude the contributions of the Gárdos channel and the K^+,Cl^- cotransporter. These transporters do not significantly contribute to cation permeability in normal red cells but may contribute more significantly in pathologic erythrocytes. Nevertheless, the estimate of monovalent cation leak is useful in understanding the pathophysiology of these permeability disorders.

Normal red cells have a low leak that falls with temperature, reaching a minimum at approximately 10°C (Figs. 16-37 and 16-38).[871] The reason for this minimum is unknown. The capacity of the Na^+,K^+ pump far exceeds the normal leak rate at physiologic temperatures, but pump activity falls sharply below room temperature and approximates the normal leak at 0°C (see Fig. 16-38). The temperature profile of the passive leak varies in each disorder (see Fig. 16-37). In classic OHSt, the leak rate, particularly of the Na^+ leak, is extremely high at body temperatures and exceeds the capacity of the Na^+,K^+ pump, which leads to cell swelling and hemolysis (see Fig. 16-37, *A*). Stomatocytosis patients with milder leaks are better compensated by the Na^+,K^+ pump and experience less hemolysis (see Fig. 16-37, *A*).[852] Patients with cryohydrocytosis have a similar mild to moderate cation leak at body temperature, causing mild to moderate hemolysis. However, in cryohydrocytosis, the cation leak increases dramatically at below-ambient temperatures,

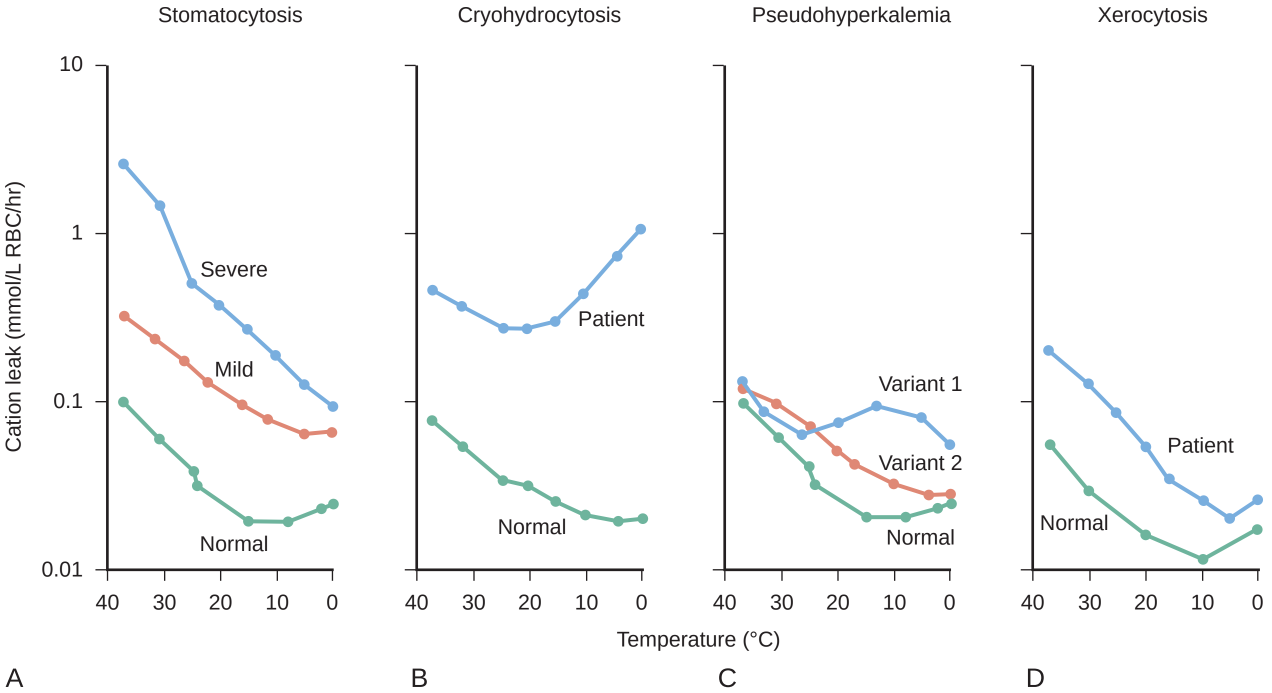

Figure 16-37 Passive permeability of monovalent cations as a function of temperature in the hereditary stomatocytosis-xerocytosis disorders (*blue* and *red circles*) compared with normals *(green circles)*. Stomatocytosis (**A**), cryohydrocytosis (**B**), pseudohyperkalemia (**C**), and xerocytosis (**D**) red cells are shown. Passive permeability is defined as the uptake of $^{86}Rb^+$ across the red cell membrane in the presence of ouabain (to inhibit the Na^+,K^+-ATPase pump) and bumetanide (to inhibit the $Na^+,K^+,2Cl^-$ cotransporter). *RBC*, Red blood cell.

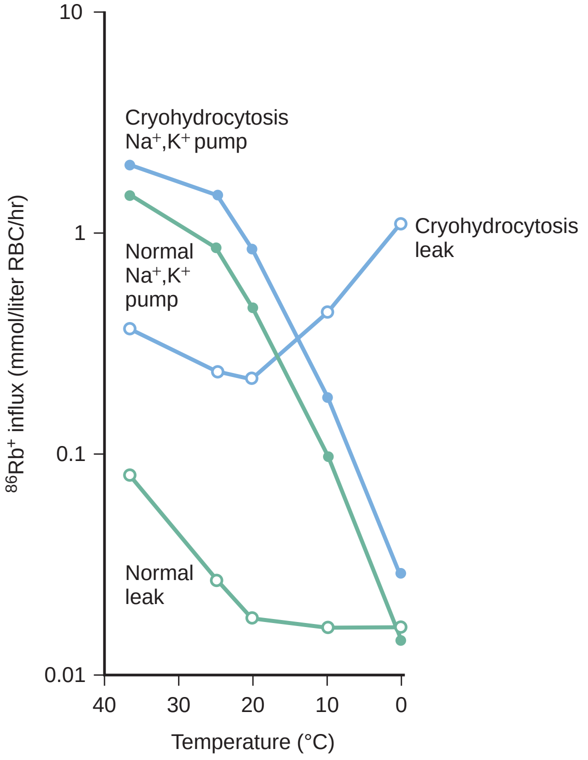

Figure 16-38 Comparison of passive monovalent cation permeabilities *(open circles)* and the capacity of the Na$^+$,K$^+$ pump *(solid circles)* in hereditary cryohydrocytosis *(blue circles)* and normals *(green circles)*. Note that the rate of cation leak exceeds the pump rate in cryohydrocytosis at low temperatures, causing the cells to swell and hemolyze. *RBC*, Red blood cell.

exceeding the capacity of the Na$^+$,K$^+$ pump below 10°C to 15°C and causing severe hemolysis (see Figs. 16-37, *B* and 16-38).

Individuals with pseudohyperkalemia typically have a nearly normal cation leak at physiologic temperatures and, therefore, little or no hemolysis. The slope of the leak is flatter than normal and sometimes even rises at below-ambient temperatures, so that K$^+$ loss occurs during storage room temperature (see Variant 1 in Fig. 16-37, *C*).

The temperature profile of the cation leak in HX parallels the normal temperature profile, but the leak is threefold to fourfold greater (see Fig. 16-37, *D*). Although the leak is relatively small, it favors K$^+$, which creates a problem because the Na$^+$,K$^+$ pump extrudes three Na$^+$ ions for every two K$^+$ ions returned. The red cell cannot compensate for leaks of K$^+_{out}$ relative to Na$^+_{in}$ that exceed the normal 2:3 ratio. Therefore the pump exacerbates the loss of intracellular cations and water and likely contributes to the dehydration of xerocytes.

Other Disorders Characterized by Stomatocytosis

A variety of conditions other than membrane permeability defects are associated with stomatocytosis (Table 16-13).

Acquired Stomatocytosis

In normal individuals, 3% or less of the red cells on peripheral blood smears are stomatocytic,[872,873] although more stomatocytic forms are evident (≤10%) if sensitive techniques such as scanning electron microscopy are used.[874] Because stomatocytes may occasionally occur as a drying artifact in limited areas of the smear, one must take care to examine multiple areas on several smears before diagnosing stomatocytosis. In wet preparations, stomatocytes are bowl shaped (uniconcave). Such preparations are useful in excluding artifactual stomatocytes, but the presence of bowl-shaped cells cannot be used as proof of stomatocytes, because target cells are also bowl shaped in solution.[875]

Drugs. In a prospective study of 4291 peripheral blood smears, Davidson and coworkers[876] found increased numbers of stomatocytes in 2.3% of the preparations. Fifty-nine percent of these smears had 5% to 20% stomatocytes, 35% had 20% to 50% stomatocytes, and 6% had more than 50% stomatocytes. In this and other studies, a wide variety of drugs and diagnoses were associated with stomatocytosis.[811,875-879] Examples of such drugs include phenothiazines, taxanes, vinca alkaloids (e.g., vincristine and vinblastine), and perflurane. Further studies are needed to determine which associations are specific and reproducible and which occur in vivo as well as in vitro. As discussed in Chapter 15 in the section on the bilayer couple hypothesis, amphiphilic, lipid-soluble drugs can cause red cells to assume a stomatocytic shape if the drug partitions preferentially into the inner half of the lipid bilayer. The affected red cells are misshapen but are not cation loaded or overhydrated and do not usually hemolyze. Vinca alkaloids often induce hemolysis, sometimes with increased membrane Na$^+$ permeability and stomatocytosis.[879] This is a particular problem in the rare instances in which these drugs must be given to patients with cancer who also have HS. We have seen two such patients and in both cases very severe hemolysis occurred. Presumably the explanation is that spherocytes and stomatocytes both have a decreased surface-to-volume ratio. Imposing a stomatocytic stress on HS red cells will make them even more spheroidal and hasten their demise.

TABLE 16-13 Conditions in Which Stomatocytosis Is the Predominant Morphology*

Hereditary stomatocytosis
Hereditary cryohydrocytosis

Rh$_{null}$ and Rh$_{mod}$ blood groups†
Adenosine deaminase hyperactivity hemolytic anemia†
Tangier disease†
Acute alcoholism†
Certain drugs (phenothiazines, taxanes, vincristine, perflurane)†
Marathon runners†
Hereditary xerocytosis†

*Normal: ≤3% stomatocytes.
†Sometimes the predominant morphology.

Alcoholism. Acquired stomatocytosis is common in alcoholics, particularly in those with acute alcoholism, and may be associated with moderate hemolysis.[872,873] Red cell cation measurements have not been reported; however, severe hydrocytosis is unlikely, because osmotic fragility tests have been normal.[872]

Long-Distance Runners. Some marathon and long-distance runners transiently develop stomatocytosis immediately after completing a race.[880,881] The effect is mild; 13% stomatocytes were seen immediately after a race versus a baseline of 4% stomatocytes.[881]

Rh Null and Rh Mod Disease

The Rh(D) antigen and the other antigens of the Rh group (cCeE) are part of two minor red cell membrane proteins encoded by two closely linked genes, one encoding the D polypeptide and the other encoding the Cc/Ee proteins; they are discussed in detail in Chapter 36. Some patients who lack all Rh antigens (Rh_{null})[882] have a moderately severe hemolytic anemia (^{51}Cr-labeled red cell half-life of 10 to 14 days)[883-886] characterized by stomatocytosis and spherocytosis. The underlying defects are in the Rh genes themselves or in the RhAG gene (also called Rh50), an ammonium transporter that is part of the Rh complex in the membrane.[887-889] Interestingly, as noted earlier, missense mutations in RhAG that alter its transport channel are also responsible for OHSt. Osmotic fragility is mildly increased in Rh_{null} disease,[883,886,890] and ektacytometry analysis shows a significant loss of membrane surface, particularly in denser (and presumably older) cells.[883] Red cell membrane K^+ or Rb^+ (a K^+ analogue) permeability is about twice normal.[883,891] Mild stomatocytosis and hemolysis are also features of Rh_{mod} disease,[892] a related anomaly, in which the expression of Rh antigens is suppressed but not absent, also owing to defects in RhAG.[887,889]

Mediterranean Stomatocytosis with Macrothrombocytopenia (Phytosterolemia or Sitosterolemia)

The hematologic aspects of this disorder—stomatocytosis with mild to moderate hemolytic anemia, splenomegaly, normal red cell cations, a normal osmotic fragility, and macrothrombocytopenia (40,000 to 150,000 platelets of 3 μ^3 to 120 μ^3 in size; Fig. 16-39)[893]—were first observed in Mediterranean individuals who migrated to Australia,[878] the population that gave the disorder its name. Tendon and tuberous xanthomas, a high cholesterol level, and a strong tendency toward premature atherosclerosis (sometimes even symptomatic in adolescents) are also features of the disease. The large platelets aggregate poorly in response to ristocetin, and some patients have a bleeding tendency.[894] We now know that these are manifestations of a rare inherited metabolic condition called phytosterolemia (or sitosterolemia), in which the absorption of all sterols, including both cholesterol and plant sterols (phytosterols, of which sitosterol is one of several that are elevated), is massively increased.[894] Phytosterolemia is caused by homozygous or compound heterozygous mutations in either the ABCG5 or ABCG8 gene.[894,895] The product of these genes normally forms a dimeric-ATP–binding cassette protein in the enteric mucosa, which aids in rejecting sterols into the gut. In retrospect some previously reported patients with phytosterolemia have also had stomatocytosis and hemolysis.[896] Plasma lipoproteins and red cell membranes contain excess plant sterols in this disease,[894] and these are presumably directly responsible for the defects in red cell shape and survival, and in platelet size and function. Diets high in vegetable oils, such as olive oil, aggravate the disease; this finding may explain why it was initially observed in Mediterranean immigrants in Australia.[894]

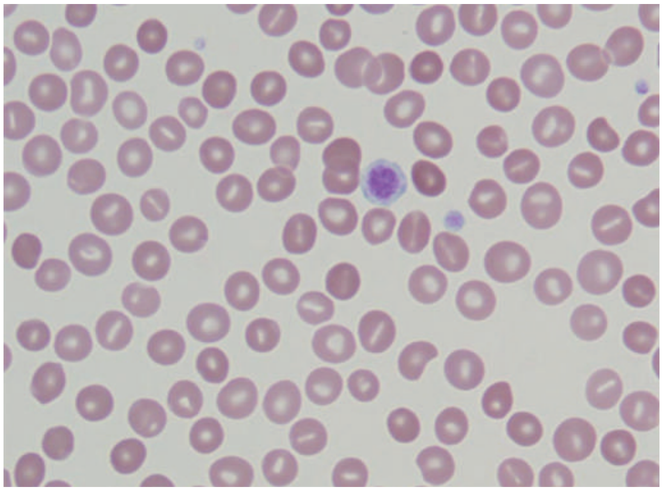

Figure 16-39 Peripheral blood smear from a patient with stomatocytosis and macrothrombocytopenia, so-called Mediterranean stomatocytosis, due to phytosterolemia (or sitosterolemia). Note the giant platelet fragment in the right center. *(From Neff AT: Sitosterolemia's stomatocytosis and macrothrombocytopenia.* Blood *120:4283, 2012.)*

ACQUIRED DISORDERS OF RED CELL MEMBRANE LIPIDS

Spiculated Red Cells: Echinocytes and Acanthocytes

There are two basic types of spiculated red cells, echinocytes and acanthocytes. Echinocytes typically have a serrated outline with small, uniform projections more or less evenly spread over the circumference of the cell, whereas acanthocytes have a few spicules of varying size that project irregularly from the red cell surface. These differences are easily detected in scanning electron micrographs and can usually be discerned in wet preparations, but it is often quite difficult to make the distinction in dried smears. In general, echinocytes appear crenated in smears, that is, as cells with relatively uniform scalloped edges, whereas acanthocytes appear contracted, dense, and irregular (Fig. 16-40).

Echinocytes are readily produced in vitro by washing red cells in saline,[897] by the interaction of red cells with glass surfaces,[897] by amphipathic molecules that partition into and expand the outer one half of the lipid bilayer,[898] and by molecules that inhibit band 3 transport.[898] High pH values, ATP depletion, and Ca^{2+} accumulation also cause echinocytosis.[899-901] In vivo, echinocytes are most often found in patients with advanced uremia[901] or with

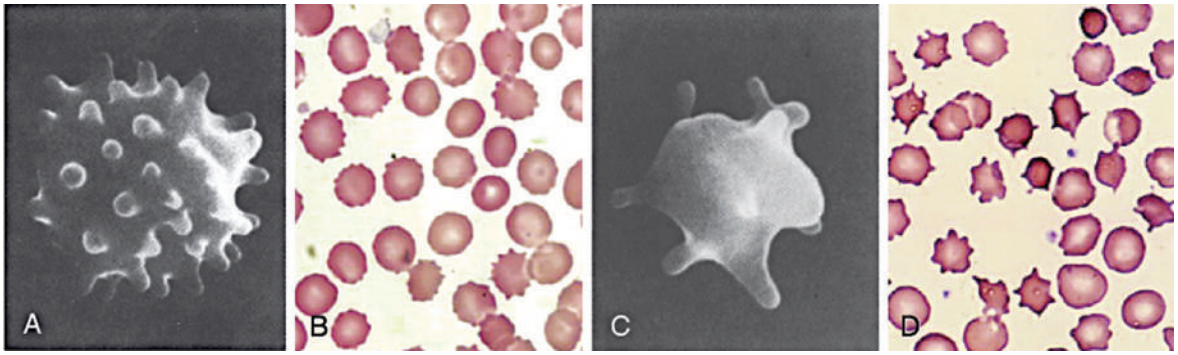

Figure 16-40 Morphology of echinocytes and acanthocytes. **A**, Scanning electron micrograph of a spherocytic echinocyte. **B**, Peripheral blood smear of echinocytes. **C**, Scanning electron micrograph of an acanthocyte. **D**, Peripheral smear of acanthocytes in a patient with spur cell anemia.

defects of glycolytic metabolism,[902] in patients after splenectomy,[897] and in some patients with microangiopathic hemolytic anemias (Table 16-14). Echinocytes are also commonly seen in neonates, especially those who are premature,[903] and in divers after decompression from pressures of more than 3 to 4 bar.[904] They are seen transiently after transfusions with large amounts of stored blood, because red cells become echinocytic after a few days of storage. Acanthocytes and echinocytes may be found in patients with neuroacanthocytoses,[905,906] severe hepatocellular damage,[907] infantile pyknocytosis,[908] anorexia nervosa,[909,910] In(Lu) blood groups,[911] and hypothyroidism (see Table 16-14).[912] Occasionally, they are the predominant morphologic feature in patients with myelodysplasia.[913,914]

The anemia seen in patients with liver disease has a complex etiologic pattern. Common causes include blood loss, hypersplenism, iron deficiency, folic acid deficiency, and marrow suppression from alcohol ingestion, hepatitis virus infection, and other poorly understood factors.[915,916] These conditions are discussed elsewhere in this text.

Hypothyroidism*

*Disorder sometimes associated with spiculated red cells.

In addition, in some patients, acquired abnormalities of red cell membrane lipids may contribute to anemia. Two morphologic syndromes are recognized. In one, target cells predominate. In the other, a syndrome of brisk hemolysis develops in association with acanthocytes or "spur" cells, so-called *spur cell anemia* (see Fig. 16-40, *D*).[907,916-935] Typically, target cells are associated with obstructive liver disease, and acanthocytes are associated with hepatocellular disease. In practice, the situation is more complex. It is not uncommon for both cell morphologic findings to coexist, and some experimental data suggest that they are different stages of the same process. For example, when the bile duct is ligated in a rat, acanthocytes appear within 8 hours, but they convert to target cells if the obstruction persists for 7 days or more.[936] Nevertheless, acanthocytes (spur cells) and target cells differ in many important respects, and will be treated here as if they result from distinct pathophysiologic processes.

Spur Cell Anemia

Spur cell anemia has mostly been described in patients with alcoholic cirrhosis.[907,918-920,931,932] However, it is also reported in those with cardiac cirrhosis,[919] metastatic liver disease,[923] liver transplantation,[933] hemochromatosis,[922] neonatal hepatitis,[926] cholestasis,[916,917] Wilson disease,[937] and severe acute hepatitis.[937] The range of diseases in which spur cells are found suggests that it may occur in any disease in which damage to hepatocytes is severe. Not all patients with hepatocellular disease have spur cells or anemia, but their presence is a bad prognostic sign in adults.[934] Whether that is also true in children is unknown.

Typically, patients have moderately severe hemolysis (hematocrit of 20% to 30%), marked indirect hyperbilirubinemia, splenomegaly, and clinical and laboratory evidence of severe hepatic dysfunction. By definition, more than 20% acanthocytes are evident in multiple areas on several peripheral blood smears. Morphologically, the acanthocytes of spur cell anemia are indistinguishable from those seen in patients with abetalipoproteinemia. In

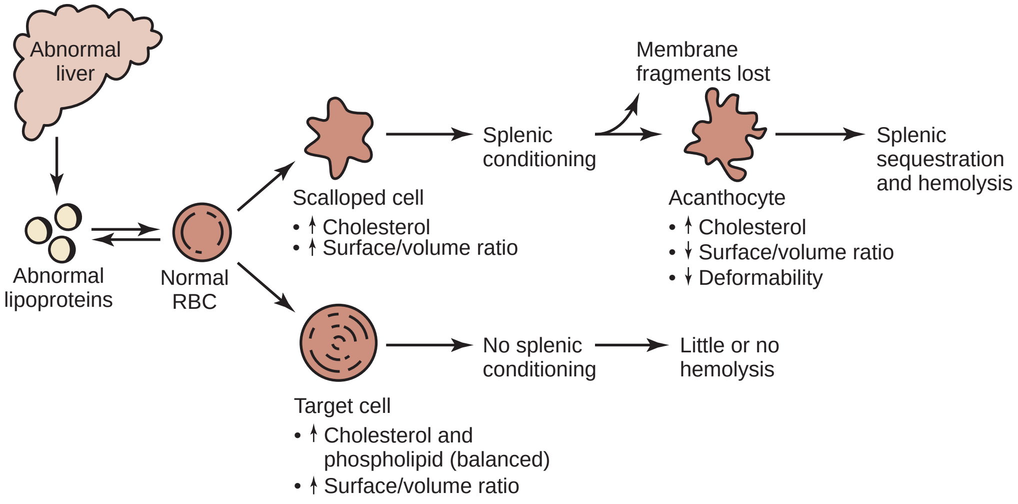

Figure 16-41 Schematic illustration of the pathophysiology of acanthocyte (spur cell) and target cell formation in liver disease.

some patients significant numbers of echinocytes and target cells may be present, and spherocytes may develop, presumably as a result of vesiculation. Occasionally, this may cause some diagnostic confusion. In our experience, however, many of these "spherocytes" have fine spicules, evident on close examination, a finding that distinguishes them from true microspherocytes.

The red cell life span of spur cells is markedly shortened because of splenic sequestration,[907,919,924,927] and, as expected, hemolysis abates after splenectomy.[927] Unfortunately, splenectomy is a dangerous and often fatal procedure in these very sick patients and is not generally recommended.[928] In addition, spur cell anemia has been reported in a splenectomized patient.[921] Some success has been reported in treating the anemia of these patients with phospholipid infusions[928]; flunarizine[929]; or a combination of flunarizine, pentoxifylline, and cholestyramine[938]; however, these approaches are still experimental. Cure of the anemia is obtained through liver transplantation,[939] but the disease recurs if the transplant fails.[940]

The clinical syndrome of spur cell anemia can be produced by at least two different pathogenic mechanisms. In one group, typically consisting of patients with alcoholic cirrhosis,[907,920,925] the disorder is due to an acquired abnormality of red cell lipids. The pathophysiology of spurring in these patients was defined by Cooper and his associates many years ago[907,927,930,931] and is illustrated in Figure 16-41. It occurs in two stages: cholesterol loading and splenic remodeling. In the first stage, abnormal, cholesterol-laden, apolipoprotein AII–deficient lipoproteins, produced by the patient's diseased liver, transfer their excess cholesterol to circulating erythrocytes and increase the membrane cholesterol concentration, the cholesterol-to-phospholipid ratio (Fig. 16-42), and the membrane surface area.[932] This is an acquired process and can be mimicked in vitro by incubation of normal red cells in spur cell plasma[907,927] or in artificial media containing cholesterol-phospholipid dispersions with a cholesterol-to-phospholipid ratio greater than 1. In scanning electron micrographs, these cholesterol-laden cells are flattened and often folded, with an undulating periphery.[931] They appear scalloped or crenated on dried smears.[907,927] In vivo, in the second stage, scalloped cells are converted into spur cells by a process of splenic conditioning (see Fig. 16-41). Over a period of 1 to 7 days, membrane lipids and surface area are lost; cellular rigidity increases, presumably because of the decline in surface-to-volume ratio; and the cell assumes a typical acanthocytic form.[907,927] Splenectomy prevents both the formation of spur cells and their premature destruction; however, as noted earlier, it is a high-risk procedure in someone with severe liver disease and is seldom indicated.

The cholesterol-laden, incipient spur cell is presumably detained and remodeled by the spleen because it is less deformable than normal. The molecular explanation for this change in deformability is unknown. The involvement of band 3 is suggested by the acanthocytic morphologic findings of rare individuals carrying the band 3 HT

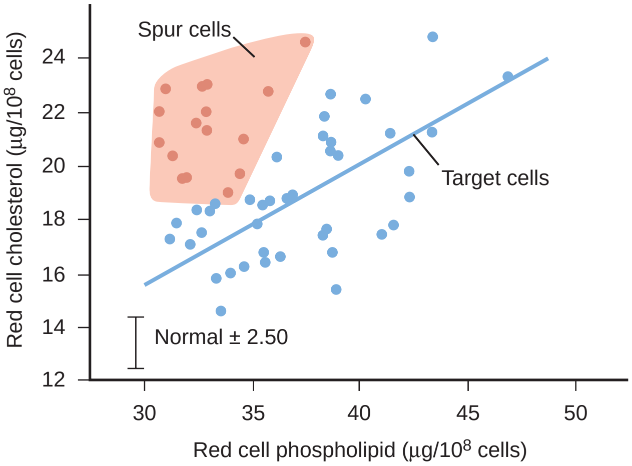

Figure 16-42 The cholesterol and phospholipid content of target cells *(blue circles)* and spur cells *(orange circles)*. Note that target cells tend to have a balanced increase in cholesterol and phospholipid, whereas spur cells are usually selectively enriched in cholesterol. *(Modified from Cooper RA, et al: An analysis of lipoproteins, bile acids, and red cell membranes associated with target cells and spur cells in patients with liver disease.* J Clin Invest *51: 3182–3192, 1972.)*

variant.[941] Wong believes that an increase in inward-facing band 3 molecules contracts the membrane skeleton and causes echinocytosis or acanthocytosis, whereas an increase in outward-facing band 3 molecules causes stomatocytosis,[942] but there is no direct evidence for this interesting hypothesis.

Other studies have identified a defect in phospholipid repair.[943] Spur cells and cholesterol-laden normal red cells have decreased fatty acid acylation of phospholipids. Furthermore, red cell membrane lipid “rafts” are cholesterol-rich microdomains that contain unique proteins.[944,945] Changes in the intracellular electrolytes cause shedding of these lipid “rafts.”[946] It is unclear whether increasing the membrane cholesterol would further increase this process. All of these processes may play a role in this anemia, but further studies are needed to better understand this process.

A second group of patients with liver disease and spur cell anemia differs in that red cell membrane lipids are normal and incubation of normal red cells in the patients’ plasma does not induce spurring.[919,923,924] The pathophysiology of this condition is unknown and largely unstudied. It has been reported in patients with alcoholic cirrhosis[919,924] and metastatic liver disease.[923] This is the form of the disease that the author has most often seen in children with spur cells and severe hepatocellular dysfunction.

Obstructive Liver Disease: Target Cells

Red cells increase their surface area by an increase in membrane lipids. In dried smears the excess surface accumulates and bulges outward in the red cell’s central clearing, producing the characteristic target cell morphologic pattern (Fig. 16-43). Target cells are also seen when red cell volume is diminished, owing to decreased hemoglobin synthesis (e.g., thalassemia or iron deficiency), abnormal hemoglobin charge or aggregation (e.g., hemoglobins S, C, D, and E), or decreased cell cations and water (Table 16-15). In these instances there is a relative increase in the surface-to-volume ratio. With the exception of dehydrated red cells, an increase in membrane surface, whether relative or absolute, has little effect on red cell deformability or life span and hence is usually innocuous.

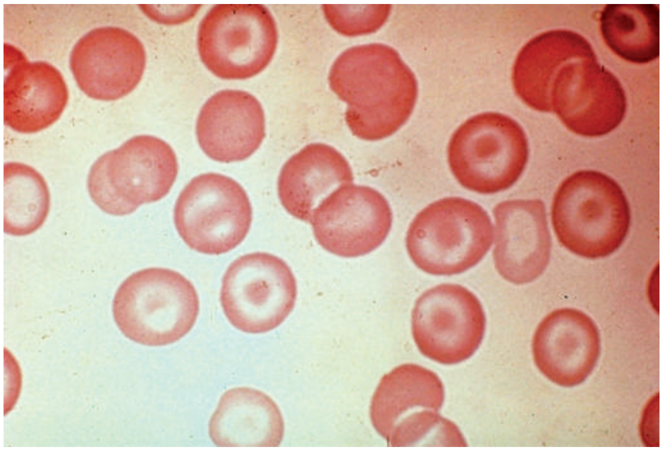

Figure 16-43 Target cells in obstructive liver disease. In contrast to the target cells in hypochromic-microcytic anemias, the target cells in liver disease are normal to large in size and well hemoglobinized.

Target cells are particularly characteristic of biliary obstruction[875,947] but also occur in other forms of liver disease. Like spur cells, they form when red cells accumulate excess lipids from abnormal lipoproteins (see Fig. 16-41). However, unlike spur cells, target cells are characterized by a balanced increase in both free cholesterol and phospholipids (see Fig. 16-42).[948,949] The phospholipid increase is confined to phosphatidylcholine.

The pathogenesis of lipid accumulation in target cells is relatively clear. The process is extracorpuscular and reversible and is due to an abnormal serum component. Normal cells acquire target cell surface area, morphologic characteristics, and osmotic resistance when transfused into patients with obstructive jaundice or incubated in their serum, whereas target cells from such patients lose their excess lipids and revert to biconcave discs in normal persons or their sera.[947] Cooper and coworkers[950] found a close relationship between the cholesterol-to-phospholipid ratios of target cells and serum lipoproteins, particularly low-density lipoproteins. It is known that in obstructive jaundice a unique, abnormal lipoprotein called Lp-X accumulates in the low-density lipoprotein class,[951,952] possibly caused, at least in part, by an acquired deficiency of the hepatic enzyme LCAT. Lp-X contains approximately equal molar amounts of free cholesterol and phosphatidylcholine, plus small amounts of protein, cholesterol esters, triglycerides, and lithocholic acid.[952] The ratio of free cholesterol to phospholipid in Lp-X approximates the ratio in normal red cells, which may be why the increase in lipid is not pathologic. Normal red cells rapidly acquire excess cholesterol, phosphatidylcholine, and surface area when incubated with Lp-X in vitro,[949] and it seems likely that this may be the source of lipids for membrane expansion and targeting in vivo.

Followup to reference 14, with updated recommendations.

277. Stewart GW, Amess JAL, Eber SW, et al: Thrombo-embolic disease after splenectomy for hereditary stomatocytosis. *Br J Haematol* 93:303–310, 1996.

Important study showing a high rate of serious thromboembolic complications in patients with "stomatocytosis" following splenectomy. A flawed study that confusingly lumps OHSt and HX and is anecdotal and lacks controls, but is persuasive and has led to the recommendation that splenectomy be avoided in these diseases.

294. Miraglia del Giudice E, Perrotta S, Nobili B, et al: Coinheritance of Gilbert syndrome increases the risk for developing gallstones in patients with hereditary spherocytosis. *Blood* 94:2259–2262, 1999.

Important study showing that even heterozygosity for the Gilbert polymorphism more than doubles the risk of gallstones in patients with HS.

331. Valeur-Jensen AK, Pedersen CB, Westergaard P, et al: Risk factors for parvovirus B19 infection in pregnancy. *JAMA* 281:1099–1105, 1999.

About 65% of pregnant women have evidence of a past parvovirus infection. The risk of infection is high for susceptible pregnant women exposed to an infected patient. Illustrates the importance of respiratory and contact precautions for HS patients during an aplastic crisis.

363. Hsiao M, Sathya C, Nathens AB, et al: Is activity restriction appropriate for patients with hereditary spherocytosis? A population-based analysis. *Ann Hematol* 92:523–525, 2013.

Important study, which shows the risk of blunt splenic injury due to trauma is very low in unsplenectomized patients with HS (<1 in 20,000 per person per year) and is no greater than the risk in the general population.

366. Schwartz PE, Sterioff S, Mucha P, et al: Postsplenectomy sepsis and mortality in adults. *JAMA* 248:2279–2283, 1982.

One of the best studies of the risk of overwhelming sepsis following splenectomy. Limited in that it largely precedes routine pneumococcal immunization and focuses on adults. Nevertheless, more studies like this one are needed.

378. Eraklis AJ, Kevy SV, Diamond LK, et al: Hazard of overwhelming infection after splenectomy in childhood. *N Engl J Med* 276:1225–1229, 1967.

Classic study of the risk of overwhelming sepsis following splenectomy, especially in young children. Not the first to identify the problem but probably the most influential early report.

382. Hansen K, Singer DB: Asplenic-hyposplenic overwhelming sepsis: postsplenectomy sepsis revisited. *Pediatr Dev Pathol* 4:105–121, 2001.

Follow-up to famous and influential 1973 review (reference 379).

407. Schilling RF, Gangnon RE, Traver MI: Delayed adverse vascular events after splenectomy in hereditary spherocytosis. *J Thromb Haemost* 6:1289–1295, 2008.

The definitive study to date of late adverse arterial and venous events in splenectomized patients with HS.

409. Robinette CD, Fraumeni JF, Jr: Splenectomy and subsequent mortality in veterans of the 1939–45 war. *Lancet* 2:127–129, 1977.

Classic case-controlled study of the consequences of wartime traumatic splenectomies 30 years later. Shows a near doubling of the risk of ischemic heart disease.

448. Bader-Meunier B, Gauthier F, Archambaud F, et al: Long-term evaluation of the beneficial effect of subtotal splenectomy for management of hereditary spherocytosis. *Blood* 97:399–403, 2001.

The best long-term (10- to 15-year) follow-up of HS patients treated by partial splenectomy. Patients had sustained improvement of their hemolysis and anemia and apparent stabilization of spleen size after an initial period of splenic regrowth. However, some patients with severe HS required reoperation and complete splenectomy.

558. Coetzer T, Lawler J, Prchal JT, et al: Molecular determinants of clinical expression of hereditary elliptocytosis and pyropoikilocytosis. *Blood* 70:766–772, 1987.

Severity of hemolysis in HE and HPP directly correlates with the percentage of spectrin dimer (i.e., the degree of functional impairment of spectrin self-association) and with the decrease in spectrin content.

572. Mentzer WC, Jr, Iarocci TA, Mohandas N, et al: Modulation of erythrocyte membrane mechanical stability by 2,3-diphosphoglycerate in the neonatal poikilocytosis/elliptocytosis syndrome. *J Clin Invest* 79:943–949, 1987.

Interesting hypothesis that the unusual severity of HE in some neonates results from fetal hemoglobin, not binding 2,3-diphosphoglycerate (DPG), because free DPG destabilizes the membrane skeleton.

587. Alloisio N, Morlé L, Marechal J, et al: Sp $\alpha^{V/41}$: a common spectrin polymorphism at the αIV-αV domain junction. Relevance to the expression level of hereditary elliptocytosis due to α-spectrin variants located in trans. *J Clin Invest* 87:2169–2177, 1991.

Discovery that a common polymorphism in α-spectrin (later named spectrin αLELY) is associated with decreased expression of the affected allele. If the opposite allele carries an α-spectrin mutation, such as HE, the effect is to increase the severity of the disease.

588. Coetzer T, Palek J, Lawler J, et al: Structural and functional heterogeneity of α spectrin mutations involving the spectrin heterodimer self-association site: relationships to hematologic expression of homozygous hereditary elliptocytosis and hereditary pyropoikilocytosis. *Blood* 75:2235–2244, 1990.

Shows that different α-spectrin mutations differ widely in their severity, with those located in the self-association site more severe than those located more distally.

600. Zarkowsky HS, Mohandas N, Speaker CB, et al: A congenital haemolytic anaemia with thermal sensitivity of the erythrocyte membrane. *Br J Haematol* 29:537–543, 1975.

Discovery and first report of HPP.

605. Tchernia G, Mohandas N, Shohet SB: Deficiency of cytoskeletal membrane protein band 4.1 in homozygous hereditary elliptocytosis: implications for erythrocyte membrane stability. *J Clin Invest* 68:454–460, 1981.

The first report of a defect in protein 4.1 in HE. Homozygotes had nearly complete deficiency and severe fragmentation and hemolysis. Heterozygotes had 50% deficiency and typical HE. Proof of the importance of protein 4.1 in membrane stability.

638. Liu SC, Palek J, Prchal J: Defective spectrin dimer-dimer association in hereditary elliptocytosis. *Proc Natl Acad Sci U S A* 79:2072–2076, 1982.

Classic study showing, for the first time, a defect in spectrin self-association in some patients with HE. HE membranes from these patients contain increased specrin dimer, and membrane skeletons of HE patients or of normals manipulated to convert spectrin tetramer to dimer are highly mechanically fragile.

649. Wilmotte R, Maréchal J, Morlé L, et al: Low expression allele α^{LELY} of red cell spectrin is associated with mutations in exon 40 (α V/41 polymorphism) and intron 45 and with partial skipping of exon 46. *J Clin Invest* 91:2091–2096, 1993.

Showed that spectrin αLELY is a very common polymorphism that causes exon skipping, interfering with spectrin heterodimer assembly and protein expression.

710. Jarolim P, Palek J, Amato D, et al: Deletion in the band 3 gene in malaria resistant Southeast Asian ovalocytosis. *Proc Natl Acad Sci U S A* 88:11022–11026, 1991.

Discovery that all patients with SAO have a deletion of nine amino acids at the boundary between the cytoplasmic and membrane domain of band 3.

722. Saul A, Lamont G, Sawyer WH, et al: Decreased membrane deformability in Melanesian ovalocytes from Papua New Guinea. *J Cell Biol* 98:1348–1354, 1984.

Discovery that Southeast Asian ovalocytes are very rigid, which may explain, at least in part, their resistance to invasion by malarial parasites.

723. Guizouarn H, Borgese F, Gabillat N, et al: South-east Asian ovalocytosis and the cryohydrocytosis form of hereditary stomatocytosis show virtually indistinguishable cation permeability defects. *Br J Haematol* 152:655–664, 2011.

SAO is a form of cryohydrocytosis.

750. Stewart GW: Hemolytic disease due to membrane ion channel disorders. *Curr Opin Hematol* 11:244–250, 2004.

Good review of the stomatocytosis-xerocytosis syndromes by one of the leaders in the field.

751. Gallagher PG: Disorders of red cell volume regulation. *Curr Opin Hematol* 20:201–207, 2013.

Good recent review of stomatocytosis-xerocytosis syndromes by one of the leaders in the field.

752. Zarkowsky HS, Oski FA, Sha'afi R: Congenital hemolytic anemia with high-sodium, low-potassium red cells: I. Studies of membrane permeability. *N Engl J Med* 278:573–581, 1968.

Early description and first detailed physiologic study of OHSt.

780. Montel-Hagen A, Kinet S, Manel N, et al: Erythrocyte Glut1 triggers dehydroascorbic acid uptake in mammals unable to synthesize vitamin C. *Cell* 132:1039–1048, 2008.

Remarkable discovery that interaction of stomatin with the Glut1 glucose transporter converts it into a dehydroascorbic acid transporter in mammals, such as humans, that lack the ability to synthesize ascorbic acid.

803. Glader BE, Fortier N, Albala MM, et al: Congenital hemolytic anemia associated with dehydrated erythrocytes and increased potassium loss. *N Engl J Med* 291:491–496, 1974.

Initial description and investigation of what was initially called hereditary dessicytosis, which we now call hereditary xerocytosis (HX) (or dehydrated hereditary stomatocytosis).

805. Grootenboer S, Schischmanoff PO, Laurendeau I, et al: Pleiotropic syndrome of dehydrated hereditary stomatocytosis, pseudohyperkalemia, and perinatal edema maps to 16q23-q24. *Blood* 96:2599–2605, 2000.

Description of variable features of HX in fetuses and neonates: hydrops, perinatal edema, and pseudohyperkalemia.

815. Platt OS, Lux SE, Nathan DG: Exercise-induced hemolysis in xerocytosis: erythrocyte dehydration and shear sensitivity. *J Clin Invest* 68:631–638, 1981.

A particularly well studied patient with HX, showing that dehydrated red cells are shear sensitive and that dehydration-induced shear sensitivity is not fully reversible if prolonged.

853. Miller G, Townes PL, MacWhinney JB: A new congenital hemolytic anemia with deformed erythrocytes (”stomatocytes”) and remarkable susceptibility of erythrocytes to cold hemolysis in vitro. I. Clinical and hematologic studies. *Pediatrics* 35:906–915, 1965.

Original description of hereditary cryohydrocytosis.

858. Bruce LJ, Robinson HC, Guizouarn H, et al: Monovalent cation leaks in human red cells caused by single amino-acid substitutions in the transport domain of the band 3 chloride-bicarbonate exchanger, AE1. *Nat Genet* 37:1258–1263, 2005.

Important discovery that patients with cryohydrocytosis, some milder forms of hereditary stomatocytosis, and a form of HS with a low-temperature cation leak all have missense mutations in band 3 that pervert the transport properties of the anion channel.

866. Flatt JF, Guizouarn H, Burton NM, et al: Stomatin-deficient cryohydrocytosis results from mutations in SLC2A1: a novel form of GLUT1 deficiency syndrome. *Blood* 118:5267–5277, 2011.

Discovery that patients with cryohydrocytosis associated with stomatin deficiency and mental retardation and movement disorders have unique defects in Glut1 that both impair glucose transport and convert Glut1 into a cation channel.

907. Cooper RA: Anemia with spur cells: a red cell defect acquired in serum and modified in the circulation. *J Clin Invest* 48:1820–1831, 1969.

Classic initial description and characterization of spur cell anemia. Little has been learned since that supersedes these beautiful early studies.

947. Cooper RA, Jandl JH: Bile salts and cholesterol in the pathogenesis of target cells in obstructive jaundice. *J Clin Invest* 47:809–822, 1968.

Classic study showing that target cells arise by acquiring lipids from the plasma, which increase surface area. Cross-transfusion experiments show that normal red cells acquire a target phenotype after transfusion in patients with obstructive jaundice, and vice versa.

950. Cooper RA, Diloy-Puray M, Lando P, et al: An analysis of lipoproteins, bile acids, and red cell membranes associated with target cells and spur cells in patients with liver disease. *J Clin Invest* 31:3182–3192, 1972.

Classic study distinguishing the lipid composition of target cells and spur cells in patients with liver disease.

ABNORMALITIES OF ERYTHROCYTE NUCLEOTIDE METABOLISM
Pyrimidine 5′-Nucleotidase Deficiency
Adenylate Kinase Deficiency
Adenosine Deaminase Overproduction
ACQUIRED DISORDERS OF ERYTHROCYTE GLYCOLYSIS

The mature erythrocyte, devoid of nucleus, mitochondria, ribosomes, and other organelles, has no capacity for cell replication, protein synthesis, or oxidative phosphorylation. The glycolytic production of adenosine triphosphate (ATP), the sole known energy source of erythrocytes, is sufficient to meet their limited metabolic requirements. The discovery that hemolytic anemia may result from any of several glycolytic enzymopathies has underscored the dependence of erythrocytes on glycolysis. In this chapter the clinical, biochemical, and genetic features associated with abnormalities in erythrocyte glycolysis are described in detail.

Hereditary hemolytic anemias resulting from altered erythrocyte metabolism are distinguished from hereditary spherocytosis by the absence of spherocytes on the peripheral blood smear, by normal osmotic fragility of fresh erythrocytes, by a partial therapeutic response to splenectomy, and by a recessive mode of inheritance. Hemoglobin structure and synthesis are normal. Because no specific morphologic abnormality is associated with

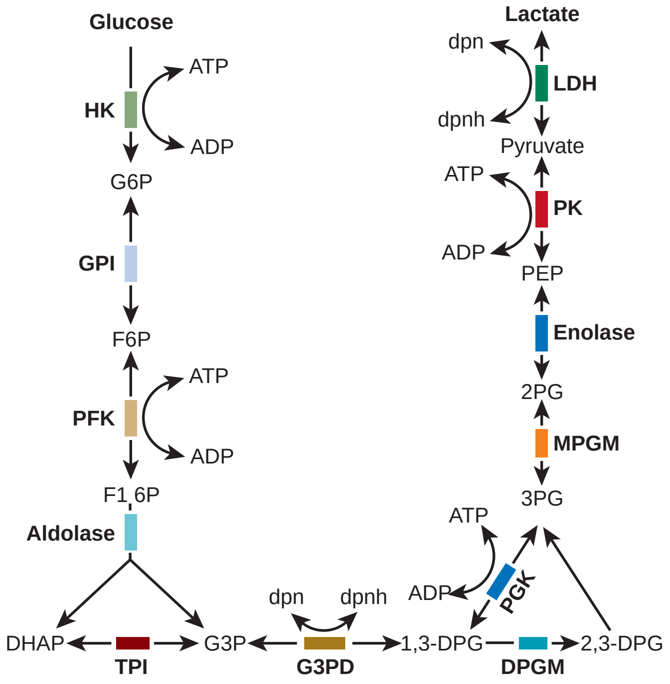

Figure 17-1 The Embden-Meyerhof pathway. Recognized enzyme defects are indicated by *solid bars*. *1,3-DPG*, 1.3-Diphosphoglycerate; *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate; *DHAP*, dihydroxyacetone phosphate; *DPGM*, 2,3-disphosphoglycerate mutase; *dpn*, nicotinamide adenine dinucleotide; *dpnh*, reduced nicotimamide adenine dinucleotide; *F1 6P*, fructose 1,6-phosphate; *F6P*, fructose 6-phosphate; *G3P*, glucose-3-phosphate; *G3PD*, glucose-3-phosphate dehydrogenase; *G6P*, glucose 6-phosphate; *GPI*, glucose phosphate isomerase; *HK*, hexokinase; *LDH*, lactate dehydrogenase; *MPGM*, monophosphoglycerate mutase; *PEP*, phosphoenolpyruvate; *PFK*, phosphofructokinase; *PG*, phosphoglycerate; *PK*, pyruvate kinase; *TPI*, triose phosphate isomerase.

these disorders, they have become known as congenital nonspherocytic hemolytic anemias (CNSHAs).[1] Although CNSHAs are usually transmitted in an autosomal recessive fashion, phosphoglycerate kinase (PGK) deficiency is an X-linked abnormality, and adenosine deaminase (ADA) overproduction is an autosomal dominant disorder. Symptoms and signs may be limited to the manifestations of hemolysis or, if the enzymopathy is present in other tissues, may involve other organ systems. The pattern of involvement of nonerythroid tissues may be of assistance in diagnosis.[2]

Initial attempts to classify these anemias were based on the autohemolysis test, in which saline-washed erythrocytes were incubated without glucose in vitro at 37° C under sterile conditions and the percentage of hemolysis was determined after 48 hours.[3,4] In 1961, Valentine and associates[5] identified a deficiency of erythrocyte pyruvate kinase (PK) in three patients with CNSHA. Subsequently abnormalities of other glycolytic enzymes have also been associated with CNSHA, as indicated in Figure 17-1. Specific alterations in protein structure underlie many of the enzyme deficiency states, and many of the underlying mutations have been identified.[6,7,8,9]

The presence of a glycolytic enzymopathy should be suspected when chronic hemolysis occurs in the absence of marked abnormalities in erythrocyte morphology or osmotic fragility. An exception to the usually unremarkable red cell morphology in CNSHA is the pronounced basophilic stippling found in pyrimidine-5′-nucleotidase (P-5′-N) deficiency.[10] Hemoglobin electrophoresis, stains for inclusion bodies, hemoglobin heat stability, acid hemolysis, and appropriate studies for immune hemolysis are normal. The autohemolysis test, previously used to screen for mutations in the glycolytic pathway, has at best limited value in the evaluation of CNSHA.[11] Unfortunately no other simple, convenient laboratory screening test has been developed that will unequivocally reveal the presence of a glycolytic enzymopathy. Therefore the appropriate diagnostic strategy for the evaluation of a suspected enzymopathy is first to eliminate easily identified causes of hemolysis, such as autoantibodies, hemoglobinopathies, or spherocytosis, before proceeding to tests for enzyme disorders.[12] Definitive diagnosis depends on quantitative assay of the activity of the suspected enzyme or identification of a specific mutation by deoxyribonucleic acid (DNA) analysis. The availability of such assays is limited, but screening tests for deficiencies in PK, triose phosphate isomerase (TPI), and glucose phosphate isomerase (GPI) can be carried out in any well-equipped clinical laboratory.[13] The in vitro properties of mutant enzyme proteins vary, and characterization of such properties has improved understanding of the genetics and pathogenesis of anemias associated with defective glycolytic enzymes (Table 17-1). Measurement of glycolytic intermediates extracted from freshly obtained erythrocytes, although potentially useful, has little clinical applicability other than the measurement of erythrocyte 2,3-bisphosphoglycerate (BPG). In contrast, measurement of intracellular metabolites is the most convenient way to screen for abnormalities in nucleotide metabolism. Red-cell ATP levels are below normal with overproduction of ADA, whereas P-5′-N deficiency is associated with increased concentrations of red-cell ATP and reduced levels of glutathione. The apparent increase in ATP is in fact the result of the presence of large amounts of cytidine

TABLE 17-1 Parameters Commonly Used In Vitro to Characterize Mutant Enzyme Protein

V_{max}	Maximal enzyme velocity obtainable with saturating substrate concentrations
K_m	The substrate concentration yielding half-maximal activity; an index of catalytic efficiency
pH optimum	The pH at which maximal enzyme activity is present
Heat stability	Resistance of enzyme protein to heat denaturation
Electrophoretic mobility	Migration of enzyme protein in an electric field
Specific activity	Enzyme activity per defined amount of enzyme protein (e.g., milligram); enzyme protein is measured immunologically with antienzyme antibodies

and uridine nucleotides, which are also measured in the enzymatic assay for ATP. Spectral analysis of a deproteinized extract of red cells provides a straightforward means of identifying such nucleotides, and it is a simple method to screen patients for suspected P-5′-N deficiency.[10]

Caution is needed in interpreting the results of quantitative assays of enzyme activity. First, only surviving cells are available for sampling in circulating blood, and the metabolic circumstances of these favored cells cannot necessarily be extrapolated to indicate the status of cells already hemolyzed. Second, assay in vitro under optimal conditions may not adequately reflect the performance of an enzyme under less favorable circumstances in vivo. Third, the high specific activity of certain enzymes in leukocytes may result in spurious normal values for erythrocyte enzyme activity unless contaminating leukocytes are removed before assay or their contribution to total activity is compensated for by appropriate calculations. Fourth, transfusion therapy with normal erythrocytes within several months before assay may obscure the presence of an enzyme defect. Fifth, the mean enzyme activity that is determined fails to portray the distribution of activity within individual erythrocytes. The endowment of intracellular enzymes is fixed, and protein synthetic ability disappears at the reticulocyte stage; thereafter the inevitable denaturation of enzyme protein that accompanies cell aging reduces enzymatic activity at a rate characteristic for each enzyme. Therefore transient accentuation of reticulocytosis is often accompanied by rising mean enzyme activity. Certain glycolytic enzymes (notably hexokinase [HK] and PK) are strikingly more active in reticulocytes than in postreticulocyte red cells, and the majority of this excess activity is rapidly lost coincident with reticulocyte maturation.[14-16] The true magnitude of an enzyme deficiency may not be apparent unless comparison is made to blood that is equally rich in reticulocytes[15] or corrections are applied that eliminate the contribution of the reticulocyte subfraction to total enzyme activity.[16]

Finally there is evidence that reversible binding of glyceraldehyde-3-phosphate dehydrogenase (G3PD), HK, and phosphofructokinase (PFK) to the band 3 membrane protein is involved in the regulation of glycolysis, and altered binding of mutant forms of these enzymes (and perhaps others) is not assessed in conventional assays performed on hemolysates.[17,18]

HEXOKINASE DEFICIENCY

Clinical Manifestations

CNSHA has been attributed to deficient erythrocyte HK activity in 24 patients (Table 17-2). Severely affected individuals may exhibit neonatal hyperbilirubinemia and thereafter require transfusion at regular intervals for intractable anemia. In patients with mild disease, the hemolysis is fully compensated for and anemia is absent. However, jaundice, reticulocytosis, and splenomegaly are usually present in such patients. Gallstones may be evident, even in early childhood.[27] Hyperhemolytic episodes are not a feature of the disorder. The results of red cell morphologic examination are usually unremarkable, but occasional burr cells, target cells, stippled cells, and densely stained spiculated cells may be observed after splenectomy. The osmotic fragility of fresh erythrocytes is normal, but a fragile population of cells may appear after incubation at 37° C.

Biochemistry

In human red cells, HK is a monomer (relative molecular mass: 112,000).[37] It is encoded by a gene (*HK1*) located on chromosome 10q22.[22] HK activity declines as red cells age. Loss of activity is particularly striking during reticulocyte maturation. In human reticulocytes, two major isoenzymes of HK have been identified by chromatographic techniques.[38] One (HKR) has an apparent half-life in vivo of only 10 days, whereas the other (HK1) has a longer half-life of 66 days. These two proteins are the products of two closely similar messenger ribonucleic acids (mRNAs) that are transcribed from a single gene (*HK1*) by the use of alternate promoters. Exon 1 is unique to each mRNA species, but the remaining 17 exons are identical.[39] Differential loss of these two isoenzymes appears to explain the biphasic character of the decay in HK activity during erythrocyte aging. An ATP- and ubiquitin-dependent proteolytic system capable of degrading about 80% of HK activity may explain the rapid loss of HK in rabbit reticulocytes,[40] or the loss may be secondary to an intrinsic property of the HK molecule itself.[41] Previous oxidative injury appears to be necessary for recognition and destruction of HK by the ubiquitin-dependent system.[42] Because ATP- and ubiquitin-dependent proteolysis is limited to reticulocytes,[40] it cannot be responsible for the loss of HK in aging human red cells.

HK is the glycolytic enzyme with the lowest activity in normal red cells, and a variety of observations indicate that it plays a rate-limiting role in erythrocyte glycolysis.[43-47] The maximal activity of erythrocyte HK from deficient patients has varied from 13% to 91% of normal (see Table 17-2). In evaluating these findings, comparisons of enzyme activity between red cell populations of equivalent age must be made. In the case described by Valentine and associates[46] (Fig. 17-2), although HK activity was 62% of the normal value for mature erythrocytes, it was only 14% of the activity found in blood with high reticulocyte counts. Separation of young and old red cell populations by centrifugation revealed only the expected moderate diminution (to 0.11 mol/min/10^{10} red blood cells) of HK activity in older cells from this patient.[47] HK activity was even lower (0.075 mol/min/10^{10} red blood cells) in an asymptomatic brother, yet no evidence of undue hemolysis was present. However, Figure 17-2 shows that the brother's cells are actually far less deficient with respect to cell age than the immature cells of the propositus. The impact of HK deficiency is clearly greater in energetic young erythrocytes, whereas cells that survive to an older age can meet their limited metabolic requirements even at very low HK levels.[48] As the erythrocyte ages, in vivo changes in stability or kinetics peculiar to mutant HK may also render older cells liable to undergo premature hemolysis. In rats and rabbits, HK from immature erythrocytes has a higher Michaelis constant (K_m) for

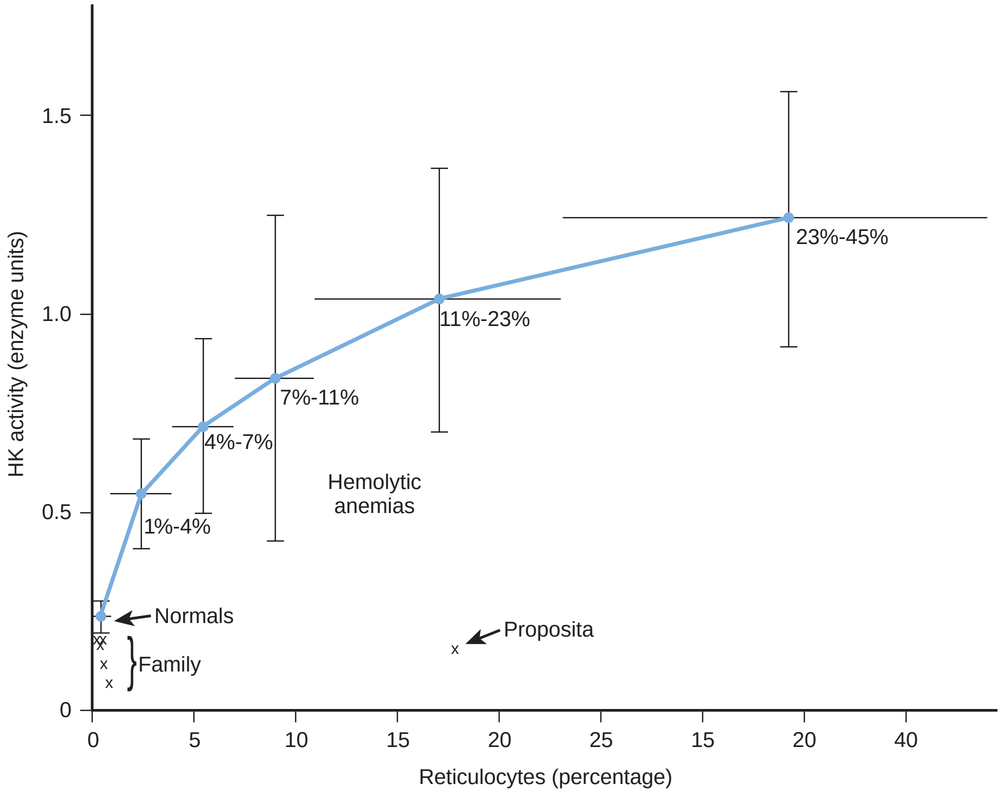

Figure 17-2 Hexokinase (HK) activity observed in 54 patients with hemolytic anemia of various causes plotted against percentages of reticulocyte in cells assayed. Patients are grouped according to reticulocyte levels. Mean HK activity for each group is plotted against the mean reticulocyte percentage in cells of that group. Standard deviations are indicated by *vertical bars*. Values for a single HK-deficient patient *(proposita)* and her family are designated separately. *(From Valentine WN, Oski FA, Paglia DE, et al: Erythrocyte hexokinase and hereditary hemolytic anemia. In Beutler E, editor: Hereditary disorders of erythrocyte metabolism, New York, 1968, Grune & Stratton, p. 288–300.)*

glucose than mature cells do, but such is not the case in normal human erythrocytes.[48]

In keeping with their enzymatic defect, HK-deficient erythrocytes have usually demonstrated subnormal glucose consumption and lactate production in vivo. Such cells also metabolize fructose poorly but utilize mannose or galactose normally,[47] because these substrates are not metabolized by HK. Some HK-deficient erythrocytes are capable of normal glucose consumption at the glucose concentrations (5 mmol/L) customarily found in plasma but utilize glucose poorly or not at all at lower glucose concentrations, either because of an abnormally low affinity for glucose[36] or because of enzyme instability under conditions of low substrate availability.[32] Such erythrocytes may encounter a particularly unfavorable metabolic environment within the spleen. The concentration of glucose in normal splenic homogenates has been found by Necheles and coworkers[36] to be only 5 to 11 mmol/g of tissue, and in a patient with HK deficiency the concentration was even lower (1.1 mmol/g of tissue). Furthermore, because splenic tissue metabolizes glucose rapidly,[49] prolonged vascular pooling in the spleen is probably accompanied by profound local hypoglycemia. Erythrocytes with unfavorable kinetics for glucose metabolism are clearly at a disadvantage in competing with reticuloendothelial cells for such a reduced glucose supply. Another disadvantage of the splenic environment is its relative acidity. The optimal pH of erythrocyte HK is approximately 8; at lower pH values, diminished enzyme activity may be expected. Possibly of greater importance, at low pH values, glucose 6-phosphate, a potent inhibitor of HK, accumulates because of PFK inhibition.[50] An erythrocyte that has diminished HK activity under optimal pH conditions will be further compromised in the acidic environment of the spleen. The clinical improvement that follows splenectomy attests to the importance of this organ in the pathogenesis of hemolysis. No splenic sequestration of chromated autologous erythrocytes was noted in two patients.[27,33] Thus in this disorder the red cells may be damaged by the spleen and die elsewhere.

Significant alterations in intracellular metabolites are associated with defective HK function. The erythrocyte ATP concentration is sometimes,[33,37] but not always[23,26,31,35] subnormal. The glucose-6-phosphate concentration is reduced to approximately half normal, and the concentrations of other more distal intermediates, most notably 2,3-BPG, are also usually reduced. These metabolites may exert a significant regulatory influence on glycolysis. For example, Brewer has shown that concentrations of 2,3-BPG in the physiologic range inhibit HK,[51] so the low 2,3-BPG levels in HK-deficient red cells may facilitate the performance of available HK. The increased affinity of hemoglobin for oxygen expected to be associated with subnormal 2,3-BPG levels has been documented in one patient with anemia and HK deficiency by Delivoria-Papadopoulos and coworkers[52] and by Oski and associates.[53] This patient, whose hemoglobin–oxygen affinity (P50) was 19 mm Hg (normal, 27 ± 1.2), was capable of just minimal exercise despite only moderate anemia (hemoglobin, 9.8 g/dL). On exercise, her central venous partial pressure of oxygen (pO_2) promptly fell to minimal levels as oxygen consumption rose. Increased oxygen delivery was achieved primarily by an increase in cardiac output, because the unfavorable oxygen affinity curve precluded any substantial further desaturation of hemoglobin.[53] Thus the altered concentration of intracellular metabolites induced by HK deficiency may, as in this patient, accentuate symptoms associated with anemia.

Because of its reactive sulfhydryl group, HK is susceptible to oxidant inactivation in the absence of sufficient glutathione.[54] Both normal and low glutathione levels have been reported in HK deficiency, but Heinz bodies have not been observed. Resting hexose monophosphate (HMP) shunt activity, measured with glucose-1 (C^{14}), was quantitatively normal in one patient despite subnormal glucose consumption, but stimulation with methylene blue was suboptimal.[47] Failure of the shunt at low glucose concentrations has also been noted in a patient with HK mutancy with a high K_m for glucose.[34] Methylene blue–stimulated methemoglobin reduction was subnormal in the single instance that it was evaluated.[19] When HK-inactivating antibodies are incorporated into normal red cells by the process of hypotonic lysis and isotonic reannealing, enzyme-deficient cells exhibit a greatly impaired response to HMP shunt stimulation by methylene blue.[44] These studies, though not indicating a central role for defective shunt activity in the pathogenesis of hemolysis, do suggest that under unusual circumstances, HK-deficient cells might be compromised by a limited shunt. Such circumstances might arise on exposure to a potent oxidant in the low glucose environment of the spleen.

Genetics

Inheritance of HK deficiency is autosomal recessive. Biochemical identification of asymptomatic carriers is not always possible, because enzyme activity often falls within the low-normal range. In a few pedigrees (see Table 17-2), the heterozygous state appears to be severe enough to result in hemolytic anemia. One such heterozygote appeared to be doubly heterozygous for HK and glucose-6-phosphate dehydrogenase (G6PD) deficiency.[55]

The qualitative abnormalities characteristic of mutant HK (see Table 17-2) may reflect either a structural or a regulatory gene mutation. On electrophoresis, mutant HK lacks one or more of the normal bands of activity, but no bands migrating in an abnormal position have been observed. The various bands represent the presence of several isozymes of HK. Diminished synthesis of one or more isozymes with predominance of the remaining isozymes accounts for the electrophoretic differences observed (see Table 17-2). DNA analysis has defined two separate *HK* mutations in a compound heterozygote who exhibited nonspherocytic hemolytic anemia.[22,56,57] One was a missense mutation (*1667T→C*) and the other was a deletion of exon 5 (96 base pairs [bp]). Expression of each *HK* mutation in a bacterial system allowed recovery of sufficient purified enzyme to determine that the missense mutation completely abolished HK activity, whereas the deletion reduced activity to about 10% of normal.[57] In another individual,[26] a homozygous missense mutation in the active site of *HK1* (*C2039→G* in exon 15) was discovered.[58] In a Japanese family, a stillborn fetus with HK deficiency was found to be homozygous for a large deletion that removed exons 5 through 8 in *HK* mRNA and led to premature termination of translation.[22] A mutation in the erythroid-specific promoter of *HK-1* inherited along with a missense mutation in exon 3 that caused aberrant splicing of both HK-R and HK-1 led to HK deficiency and mild chronic hemolytic anemia.[59] The kinetic abnormalities noted in many other mutant forms of HK undoubtedly also reflect as yet undefined structural abnormalities in enzyme protein.[*]

Studies of the tissue distribution of HK deficiency have been performed in blood cells and cultured fibroblasts. Electrophoresis of leukocyte or platelet HK reveals an anodal isozyme (HK-3) distinct from those of the erythrocyte (HK-1 and HK-2), as well as a shared isozyme (HK-1).[60,61] Leukocyte HK activity has been normal in some patients,[32,47] but the qualitative abnormality in leukocyte HK described by Necheles and colleagues,[36] as well as the case of generalized HK deficiency in all blood cells reported by Rijksen and coworkers,[26] indicates that to some extent the enzyme is under common genetic control in different tissues. When platelet HK activity has been low, platelet function has been normal despite subtle defects in in vitro energy metabolism.[62] Cultured fibroblasts from two individuals with different HK mutants contained HK with properties and activity like those found in red cells,[25] thus suggesting that this source of fetal tissue could be used for prenatal diagnosis.

A murine model of HK deficiency, termed *Downeast anemia,* is caused by homozygous inheritance of a mutation that markedly decreases the expression of HK-1 in erythroid tissues, spleen, and kidney. The mutation is the result of insertion of a transposon into intron 4 of the *HK1* gene. Mice exhibit nonspherocytic hemolytic anemia, marked reticulocytosis, splenomegaly, and striking accumulation of iron in the liver and kidney. Echinocytes and red cells split into two poles of hemoglobin connected only by thin strands of membrane are features of erythrocyte morphology in affected homozygous mice that are of interest because they have not been reported in human HK deficiency.[63]

Therapy

Treatment consists of red cell transfusion as indicated, supplemental folic acid, and close observation for cholelithiasis. Splenectomy may alleviate but does not eliminate the anemia.[†]

GLUCOSE PHOSPHATE ISOMERASE DEFICIENCY

Clinical Manifestations

A deficiency of erythrocyte GPI has been reported in more than 60 patients with congenital hemolytic anemia.[64] Hemolytic anemia usually appears in infancy and often requires red cell transfusion therapy. Hyperbilirubinemia,[65] hydrops fetalis,[66,67] or death[68] may occur during the neonatal period. Several patients have experienced hyperhemolytic crises after infections or drug exposure.[67,69,70] In some of these individuals G6PD, as well as GPI, has been deficient.[69,71] Hemolytic anemia is usually the sole clinical manifestation of GPI deficiency. A subset of patients also exhibit neurologic dysfunction.[72-75] In one patient, neuromuscular abnormalities were correlated with a severe reduction in muscle and cerebrospinal fluid GPI activity.[73] Blockade of glycolysis at the GPI step may divert the flow of glucose metabolism in the direction of glycogen synthesis. Several patients with GPI deficiency have been reported to have increased hepatic glycogen stores,[76,77] and in one, muscular fatigue was severe enough to suggest a diagnosis of glycogen storage disease.[77] Animal models of GPI deficiency and chronic hemolytic anemia have been developed in the mouse. The clinical and biochemical features of the disease in mice closely resemble those found in humans.[78,79]

Red cell morphologic characteristics are generally similar to those seen in other types of CNSHA. In patients with severe anemia, dense, spiculated, or "whiskered" microspherocytes have been noted after splenectomy. In one instance, sufficient numbers of such cells were present before splenectomy to suggest the diagnosis of hereditary spherocytosis.[80] In another, the predominant morphologic abnormality was stomatocytosis.[81] The reticulocytosis may be profound. Mean corpuscular volume is elevated (97 to 139 fL). With incubation at 37° C, a variable fraction of erythrocytes may exhibit abnormally increased osmotic fragility, whereas fresh cells are usually normal. Survival of chromated autologous red cells is reduced, often[82-84] but not invariably,[68,82,85] with evidence of splenic sequestration.

Biochemistry

GPI is a dimer[86] composed of two identical subunits, each with a relative molecular mass of approximately 60,000.[84,86] Subunit synthesis is directed by a single genetic locus on chromosome 19.[87] The crystal structure of human GPI has been defined.[88] GPI is a multifunctional protein. The dimeric form exhibits glycolytic enzyme activity, whereas the monomeric form functions as a cytokine. Monomeric GPI is 100% homologous to neuroleukin, a neurotrophic growth factor secreted by lectin-stimulated T cells[64,89,90]; to autocrine motility factor, which stimulates cell motility and the growth of metastases[91]; and to a differentiation and maturation mediator for human myeloid leukemia cells in tissue culture.[92] Altered neuroleukin function may explain the neurologic disorder associated with several GPI mutations.[64,75] Alternatively, induced GPI mutations in Chinese hamster ovary cell lines have an adverse effect on glycerolipid biosynthesis, suggesting that deficient GPI activity affects important non-glycolytic pathways.[93]

The metabolic events that precede hemolysis of GPI-deficient erythrocytes are poorly understood. Erythrocyte glycolysis is impaired in vivo, as reflected by an increased ratio of substrate to product (i.e., glucose 6-phosphate to fructose 6-phosphate) in freshly obtained GPI-deficient cells.[71,80,94-99] Paradoxically, with only occasional exceptions,[80,100] such cells are fully capable of glycolysis in vitro.[71,85,101-104] In contrast to HK deficiency, in which 2,3-BPG levels are low, sufficient glycolysis generally occurs in GPI deficiency to maintain the 2,3-BPG concentration at or above the normal level.[91,94,96,100,104] Except for three patients with diminished ATP concentrations, two of whom also exhibited reduced in vitro glycolysis for cell age,[81,87,105] the erythrocyte ATP concentration has been normal.

---

[*] References 19, 20, 24, 29, 30, 34.

[†] References 20, 24, 26, 32, 36, 47.

A profound defect in recycling of fructose-6-phosphate through the pentose phosphate pathway has been observed repeatedly in GPI-deficient red cells.[80,103,104] The increased formation of Heinz bodies[68,81] and glutathione instability[99,106] after exposure to acetylphenylhydrazine, an abnormal ascorbate cyanide test, and diminished concentrations of red cell glutathione[81,85,93,95,96] in fresh erythrocytes all suggest that diminished shunt activity in vivo may contribute to hemolysis.

With rare exceptions,[105] mutant forms of red cell GPI exhibit considerable thermal lability in vitro, thus making it likely that enzyme lability in vivo as red cells age will lead to premature metabolic collapse and hemolysis. Separation of red cells by centrifugation into young and old subpopulations has usually demonstrated accelerated decay of enzyme activity in the older cells.[85,107] Arnold and coworkers[107] simulated the in vivo process of aging by incubating red cells in vitro at 37° C for 8 days and changing the incubation medium often to ensure that glucose availability and pH remained constant. GPI activity declined by 66% in GPI-deficient red cells during incubation, with a level of only 6% of normal being reached, and lactate production, normal at the onset, was reduced to 11% of normal. In contrast, normal reticulocyte-rich blood lost only 6% of the original GPI activity after 8 days, and lactate production fell only 7%. If mannose rather than glucose was used, GPI-deficient and normal red cells made equivalent amounts of lactate, and there was little or no loss in lactate production after 8 days. The normal glycolytic rate noted with mannose, which is isomerized by mannose phosphate isomerase and thus bypasses the GPI reaction, clearly pinpoints defective GPI activity as the cause of glycolytic failure in GPI-deficient cells. ATP depletion with consequent erythrocyte rigidity and reticuloendothelial entrapment would be anticipated to follow failure of glycolysis. GPI-deficient red cells are indeed less deformable than normal cells, particularly when comparison is made to young, reticulocyte-rich populations of cells.[92,94,108,109] Goulding studied a 9-year-old patient with GPI deficiency and priapism and concluded that the priapism was the consequence of abnormal erythrocyte deformability.[110] Studies by Coetzer and Zail revealed aggregation of membrane spectrin in GPI-deficient erythrocytes.[111] The extent of the aggregation is a function of cell age.

Even reticulocytes may be severely GPI deficient.[76] Deficient reticulocytes with limited anaerobic glycolytic capability may also be incapable of effective oxidative phosphorylation in the acidic, hypoglycemic splenic environment (see Pyruvate Kinase Deficiency), thereby leading to metabolic failure and hemolysis. Large numbers of reticulocytes were found when specimens from the spleen of a patient with GPI deficiency were examined by transmission electron microscopy.[76] Furthermore, the reticulocyte count often increases after splenectomy.[68,76,83,85] Because hemoglobin levels also increase, this observation suggests survival of a population of reticulocytes that would otherwise be hemolyzed almost immediately after their release from bone marrow.

Genetics and Inheritance

Like most other glycolytic enzymopathies, GPI deficiency is inherited as an autosomal recessive trait. Heterozygotes are hematologically normal but exhibit reduced erythrocyte GPI activity (usually to about 50% of normal). They inherit one mutant and one normal GPI allele, which results in the synthesis of two unlike GPI subunits that may combine in one of three ways to form a normal homodimer, a mutant homodimer, or a heterodimer that contains both normal and mutant subunits. Electrophoresis of GPI from the erythrocytes of heterozygotes demonstrates one to three bands depending on the extent to which the charge or activity of the mutant subunit is altered. Posttranslational events, such as oxidation of enzyme protein, may alter the electrophoretic pattern and confuse its interpretation.[112,113]

GPI mutations associated with hemolytic anemia are listed in Table 17-3. Of the 31 known mutations, 2 are splice site, 3 are nonsense, and 31 are missense mutations involving a single amino acid substitution.[64,114-116] The mutations are found in 12 of the 18 exons and are generally unique to one or, at most, a few families. The rarity of GPI deficiency and the heterogeneity of the mutations identified indicate that no selective advantage is conferred to affected individuals. Half of the homozygotes or compound heterozygotes for missense mutations have mild to moderate hemolytic anemia, and half have severe anemia. In contrast, all compound heterozygotes for missense mutations and either splice site or nonsense mutations have severe hemolytic anemia. Hemolytic anemia occurs in individuals when GPI activity drops below about 40% of the normal mean activity. Substrate kinetics and the optimal pH of mutant enzymes have almost always been normal, but most mutant enzymes have exhibited varying degrees of thermal instability. Study of recombinant GPI enzyme protein generated from 16 different human mutations has clarified the relation between specific mutations, their location within the three-dimensional structure of GPI, and enzyme properties (catalytic activity, enzyme kinetics, and thermostability). Mutations at or near the active site have the most severe consequences, whereas areas more distant generally have lesser effects. Thermostability is affected by different mutations to varying degrees.[117] Short of direct detection of the mutation at the DNA level, the most useful means of classifying the numerous GPI variants reported has been on the basis of stability, electrophoretic mobility, or residual enzyme activity in red cells and leukocytes.[‡] Until DNA mutation analysis has been completed on these variants, it will not be clear how many are truly unique. Immunologic titration of functionally inactive enzyme protein in red cells indicates that some mutant GPI alleles are "silent" and

produce no detectable enzyme protein, whereas others produce structurally altered protein with varying degrees of activity and stability in vivo.[118-120]

A single GPI isozyme is present in all human tissues.[87] GPI deficiency is usually less severe in nonerythroid tissues than in erythrocytes because nonerythrocytic tissues retain the ability to synthesize GPI subunits. Clinical abnormalities outside the hematopoietic system are rare and, if present, are neuromuscular in nature. Leukocytes are capable of normal phagocytosis and chemotaxis despite a reduction in GPI activity to 25%[94] to 73%[102] of normal, but if GPI activity is more severely depressed, granulocyte function is impaired.[73,121] Similarly, platelet GPI may be only 20% to 30% of normal; however, clot formation, platelet aggregation, and other clotting studies are normal.[94,102] Prenatal diagnosis is feasible by DNA analysis if the mutations are known or by measurement of GPI activity in amniotic fluid fibroblasts[66] or chorionic villus trophoblasts.[122]

Therapy

Transfusion requirements are usually eliminated by removal of the spleen, but the anemia persists.[68,76,83,102] The postsplenectomy hemoglobin levels of 6.7 to 10.3 g/dL and reticulocyte counts of 36% to 73% observed in three siblings by Paglia and coworkers[104] reflect the magnitude of the continued hemolysis that may be present. Attempts by Arnold and colleagues[102] to enhance glycolysis in a GPI-deficient patient by intravenous administration of methylene blue or inorganic phosphate (P_i) did not have a lasting benefit.

PHOSPHOFRUCTOKINASE DEFICIENCY

Clinical Manifestations

Inherited deficiency of PFK can involve erythrocytes, muscle, or both, depending on the PFK subunit affected and the nature of the biochemical defect (Table 17-4). Although low erythrocyte PFK activity and mild hemolytic anemia are commonly found in type VII glycogen storage disease (Tarui disease), the dominant clinical feature of this disorder is exertional myopathy caused by deficient muscle PFK activity.[127,128] Physical activity is limited not by anemia but by weakness, easy fatigability, and severe muscle cramps associated with the myopathy. The disease may be evident at birth and cause death during infancy as a result of respiratory insufficiency and other complications,[129] or it may be so mild that it is not manifested until old age.[130] However, in most affected individuals the disorder is first detected during adolescence or young adulthood. The diagnosis may be suspected if no lactate is produced during an ischemic (anaerobic) forearm exercise test, but confirmation requires muscle biopsy for determination of PFK activity or noninvasive magnetic resonance imaging (MRI) studies of muscle carbohydrate metabolism.[131]

When PFK deficiency is confined to erythrocytes, there are no symptoms of myopathy, and the blood lactate response to anoxic exercise is normal.[132-134] Such patients may be hematologically normal[125,135,136] or exhibit mild to moderate hemolytic anemia.[132,136] In general, red cell morphologic characteristics are not strikingly abnormal, although prominent basophilic stippling has occasionally been noted.

Biochemistry

PFK is one of several glycolytic enzymes that reversibly bind to the inner aspect of the erythrocyte membrane. Binding, which is thought to occur between the amino-terminal position of the transmembrane protein band 3 and the adenine nucleotide binding site, located in a cleft between the two dimers that form the PFK tetramer, may serve to both activate the enzyme and protect it against proteolytic degradation during erythrocyte aging.[137]

The active form of human erythrocyte PFK is a tetramer (relative molecular mass: 380,000) composed in varying combinations of two different subunits, one identical to the M subunit found in muscle PFK and the other identical to the L subunit found in liver PFK.[138,139] The relative molecular mass of the M subunit is 85,000, and that of the L subunit is 80,000.[138] About 50% of the erythrocyte enzyme is formed from M subunits,[133,138] whereas muscle PFK is composed entirely of M subunits.[133,140] A deficiency in M subunits severely depresses muscle PFK activity and results in myopathy, but it has a lesser effect on erythrocyte PFK because residual L subunits, under separate genetic control, combine to form an active L4 tetramer of PFK. However, PFK formed entirely from L subunits is unstable to heat or dilution in vitro and is more sensitive to ATP inhibition than muscle (M4) PFK.[132] At the in vivo concentrations of ATP that are present within normal erythrocytes, the enzyme activity of L4 PFK tetramers is severely inhibited, thus possibly explaining the presence of hemolytic anemia even when enzyme activity, as measured in vitro, is approximately 50% of normal. Mice that lack the M subunit but retain

the L subunit have a disease similar to Tarui disease in humans and exhibit chronic hemolysis.[141] Most recognized examples of PFK deficiency are the result of either missing[125,127] or structurally altered[134] M subunits. An interesting exception was found in a clinically normal individual, fortuitously discovered when he volunteered to serve as a "control" during studies of red cell PFK carried out by Vora and colleagues.[125] Normal M subunits but mutant, unstable L subunits were found in his red cells. There was no myopathy, and although erythrocyte PFK was only 65% of normal, hemolytic anemia was not present, presumably because residual enzyme activity within the red cell was entirely the result of the presence of M4 tetramers of PFK. The relatively greater stability and lesser susceptibility to ATP inhibition of this form of PFK apparently allowed adequate enzyme activity under conditions normally found within the red cell in vivo.

Because of the central role of PFK in regulation of erythrocyte metabolism, it is not surprising to find that a deficiency of this important enzyme is associated with hemolysis, but the mechanism of hemolysis is not well understood. Erythrocyte sodium and potassium concentrations, sodium influx, and lactate production were normal in one patient.[131] Despite their normal glycolytic capability in vitro, deficient cells were incapable of maintaining normal ATP concentrations in vivo. The low (73% of normal) intracellular ATP concentration in these cells, though indicative of an abnormality in cellular metabolism, may also exert a positive influence by partially relieving the inhibitory influence of ATP on PFK. Extensive in vitro study of erythrocytes obtained from a Swedish family with Tarui disease and mild compensated hemolytic anemia found elevated intraerythrocytic calcium levels associated with increased calcium permeability of the erythrocyte membrane. High intracellular calcium levels activated the Gardos channel with subsequent ATP depletion, potassium depletion, increased mean corpuscular hemoglobin concentration (MCHC), and diminished erythrocyte deformability. The authors point out that the PFK and Ca^{2+} channel genes are in close proximity to one another on chromosome 12q, but the reason for abnormal Ca homeostasis remains undefined.[142,143]

The complex interaction between metabolites that may dictate actual PFK activity in vivo is illustrated by physiologic studies performed on four individuals with Tarui disease.[144] At usual levels of physical activity, the pattern of erythrocyte glycolytic intermediates clearly reflected inhibition at the PFK step, and the concentration of the important downstream metabolite 2,3-BPG was only 50% of the level found in normal red cells. After the patients had 2 days of bed rest, their red cell 2,3-BPG levels sank to just one third of normal. Subsequently ergometric exercise on a bicycle eliminated the glycolytic intermediate pattern of PFK inhibition and allowed downstream intermediates, including 2,3-BPG, to increase toward normal. Release of large amounts of inosine and ammonia from enzymopathic muscle during exercise into plasma was observed in these patients. Ammonia is a powerful activator of PFK; inosine can be metabolized to lactate by glycolytic pathways (i.e., the HMP shunt) that bypass the PFK reaction. Thus the muscle metabolic abnormalities created by PFK deficiency generate metabolites that alleviated the enzymopathy in erythrocytes. (Diversion of the flow of erythrocyte glycolysis through the HMP shunt by the block at PFK may also generate increased amounts of purines and pyrimidines from 5-phosphoribosylpyrophosphate [PRPP].) The hyperuricemia sometimes noted in individuals with PFK deficiency (see Table 17-4) may be explained on this basis.[126]

An inherited deficiency of PFK found in English springer spaniels, whippets, and wachtelhunds allows interesting comparisons to be made with the human condition.[145-149] As in humans, canine PFK deficiency is an autosomal recessive disorder. Red cell PFK levels are only 7% to 22% of normal in homozygotes because the muscle subunit, which is lacking, accounts for the majority of the available subunits in normal dog red cells.[150] PFK deficiency in dogs is associated with severe hemolytic anemia. Newborn dogs are not anemic, because there is a greater abundance of L subunits and thus of functional PFK enzymes in their red cells. Hemolytic anemia appears because the normal developmental pattern of replacement of L by M subunit synthesis occurs in a setting in which M subunits either are not synthesized or are defective.[151]

A unique feature of PFK deficiency in dogs is episodic hemolysis induced by hyperventilation during exercise, mating, barking, or other similar activities.[147] Dog red cells with high sodium levels exhibit spontaneous hemolysis at alkaline pH; even the small pH change induced by hyperventilation is sufficient to generate the effect in PFK-deficient animals. Underlying the susceptibility of PFK-deficient dog red cells to hyperventilation-induced hemolysis may be their low 2,3-BPG levels, which increase intracellular pH. Raising 2,3-BPG levels to normal in vitro normalizes the response to alkalinity.[152] In comparison to humans, there is less evidence of exertional myopathy, even though dog muscle PFK activity is nearly absent,[153] because dogs do not rely on anaerobic glycolysis for generation of energy during exercise.[154] During exercise, PFK-deficient dogs do exhibit less extraction of oxygen from hemoglobin than normal dogs do, either because the affinity of hemoglobin for oxygen is high (caused by low 2,3-BPG levels in their erythrocytes) or because oxidative metabolism is impaired.[155]

PFK activity in erythrocytes from newborn infants is about 50% to 60% of that in normal adult cells.[156] PFK deficiency is more evident in older cells made earlier in gestation, perhaps because of accelerated enzyme decay.[157] Vora and Piomelli[158] showed that 25% to 30% of newborn erythrocyte PFK consists of L4 isozyme, with the remainder being divided equally between three hybrid isozymes of L and M subunits (LlM3, L2M2, and L3Ml). The L4 isozyme, not found in normal adult red cells, is unstable and presumably accounts for the reduced PFK activity of older cord red cells. The demonstration that PFK deficiency may result in hemolytic anemia in adults suggests that the enzyme deficiency characteristic of normal newborn red cells may contribute to their shortened survival.

Genetics and Inheritance

The gene locus for the L subunit of PFK has been assigned to chromosome 21, whereas the M subunit locus is on chromosome 12.[126,159] The erythrocytes, but not the leukocytes and platelets of individuals with trisomy 21, consistently contain increased PFK activity.[160] Increased erythrocyte PFK activity is caused by increased amounts of L subunit, consistent with a simple gene dosage effect.[126]

Inheritance is autosomal recessive. Type I PFK deficiency (Tarui disease), which is found predominantly in Ashkenazi Jews and Japanese individuals, is the result of mutations involving the *PFKM* gene.[161,162] The 15 reported mutations[159,163] (5 splice site, 8 missense, 1 nonsense, and 1 frameshift) are shown in Figure 17-3.[163] The widely scattered location of the mutations makes it difficult to correlate genotype and phenotype. In PFK-deficient dogs, a missense mutation involving 120 nucleotides from the 3′ end of the coding region produces a truncated mRNA and an unstable PFKM subunit tetramer with altered kinetic properties.[164,165]

Therapy

Supportive care with red cell transfusions as needed and daily folic acid supplementation are the mainstays of therapy for hemolytic anemia.

ALDOLASE DEFICIENCY

Clinical Manifestations, Biochemistry, and Genetics

Aldolase A is found in erythrocytes, muscle, and the fetal brain. Only six individuals with CNSHA and erythrocyte aldolase deficiency have been reported. Their clinical course has varied, with one also exhibiting mental retardation, three an associated myopathy, and two no abnormalities other than hemolytic anemia (Table 17-5). Two members of a Japanese family who had a severe

deficiency of red cell aldolase[166] exhibited severe chronic hemolytic anemia, sometimes exacerbated by infections. In vitro, red cell glycolysis and HMP shunt activity were depressed, thus indicating that the deficiency of aldolase was of functional significance. Both parents were hematologically normal but had intermediate reductions in red cell aldolase A activity. The mutant aldolase was strikingly thermolabile. A missense mutation (**GAT→*GGT*) giving rise to a single amino acid substitution (Asp→Gly) at position 128 was present in the mutant enzyme.[167] Transfection of *Escherichia coli* with an expression plasmid containing normal, mutant, or modified (by site-directed mutagenesis) aldolase A–complementary DNA (cDNA) generated functional aldolase molecules that were used to confirm that the amino acid substitution at position 128, a site distant from the catalytic site but within an exposed hinge region, was responsible for enzyme thermolability.[168]

In a German child, homozygosity for a point mutation at residue 206 (Glu→Lys) in the coding region of aldolase A also led to thermolability and severe enzyme deficiency in both erythrocytes and skeletal muscle.[169] Unlike the Japanese subjects, this child had a metabolic myopathy, as well as mild to moderate hemolytic anemia. The mutation at residue 206 would be predicted to disrupt the main subunit interface of the aldolase tetramer and cause thermolability. Why myopathy was noted in one setting but not in the other is unknown.

A girl of Sicilian ancestry whose red cell aldolase activity was less than a quarter of normal also exhibited myopathy and chronic hemolytic anemia.[170] Elevated plasma creatine phosphokinase activity was noted with febrile illnesses. She died at the age of 54 months of rhabdomyolysis and hyperkalemia during an acute febrile illness. Like the German patient, her aldolase A enzyme was thermolabile, which offered an explanation for the exacerbation of myopathy during fever.[171] DNA analysis revealed two mutations in the aldolase A gene in this patient: one was a premature stop codon mutation (*931*C→T*), and the second was a missense mutation (*1037*G→A*) that conferred thermolability on the enzyme.[170,171]

Another patient with aldolase deficiency exhibited CNSHA, mental retardation, mild glycogen storage disease, intestinal lactase deficiency, growth retardation, and peculiar facial features. Enzyme activity was approximately 15% of normal in erythrocytes and cultured skin fibroblasts.[172] No structural abnormality of residual erythrocyte aldolase was detected by electrophoresis, isoelectric focusing, heat stability studies, or kinetic examination. The patient was the offspring of a consanguineous marriage, but both parents were hematologically normal and had normal red cell aldolase activity.

A sixth patient, heterozygous for a thermostable mutation of aldolase A, had myopathy, arthrogryposis multiplex congenita, and hypopituitarism but normal IQ and no evidence of hemolytic anemia.[173,174] Because both parents were clinically normal, the aldolase mutation in the patient may have no relationship to his clinical abnormalities.

TRIOSE PHOSPHATE ISOMERASE DEFICIENCY

Clinical Manifestations

An association with TPI deficiency has been documented in approximately 50 patients with congenital hemolytic anemia.[175-185,186-191] In addition to chronic hemolysis, a severe neuromuscular disorder characterized initially by spasticity and psychomotor retardation and often progressing to weakness and hypotonia has been found in nearly all patients surviving beyond the neonatal period. Increased susceptibility to bacterial infection has also been noted. The neurologic abnormalities are not usually manifested before 6 to 12 months of age and are progressive, with death occurring before the age of 5 years. Occasionally, these abnormalities may stabilize during childhood[192] or adolescence.[176] In a Hungarian family, one adult son with severe TPI deficiency had extrapyramidal neurologic symptoms, whereas his older brother, who was equally TPI deficient, remained free of symptoms.[188,193] Further investigation has shown that these brothers both inherited the same two TPI mutations (see “Genetics and Inheritance” section) but that levels of dihydroxyacetone phosphate (DHAP), methylglyoxal, and advanced glycation end products were much higher in the neurologically affected brother.[194] The basis for the prolonged survival of both brothers and their different neurologic status is unknown, but epigenetic factors are suspected.

Anemia is variable, but most patients require at least occasional blood transfusions. Macrocytosis and polychromatophilia are evident on the blood smear because of the presence of reticulocytosis, which may reach 50% on occasion. Aside from occasional small, dense spiculated cells, no striking changes in erythrocyte morphologic characteristics are present.

Biochemistry

TPI is a homodimer whose two subunits (relative molecular mass: 26,750[195]) are the product of a single locus on the short arm of chromosome 12.[196] Posttranslational modification of one or both subunits may occur by deamidization of aspartines at positions 15 and 71, thereby resulting in multiple forms of the enzyme.[197,198] The 248–amino acid sequence of human (placental) TPI has been determined directly[195] and is nearly, but not completely, identical to the sequence predicted by nucleotide analysis of adult human liver cDNA.[181]

TPI is a classic housekeeping gene, present in all tissues, with an amino acid sequence that has been remarkably well conserved during evolution.[199] The eight-stranded αβ-barrel structure of the human enzyme has been confirmed at 2.8-nm resolution by x-ray crystallography.[199] TPI has no requirement for cofactors or metal ions, and there is no evidence of cooperativity or allosteric interactions between subunits.

When measured in vitro, erythrocyte TPI activity is approximately 1000 times that of HK, the least active glycolytic enzyme. Even TPI-deficient erythrocytes exhibiting only 2% to 35% of normal TPI activity in vitro possess far more TPI than HK activity. Not surprisingly, TPI-deficient erythrocytes are capable of normal glycolysis in vitro, even when compared with reticulocyte-rich normal blood.[176] Furthermore, mathematical modeling shows that increased activity of glycolytic kinases can lead to normal conversion of glucose to lactate in TPI-deficient cells.[200] Nonetheless, DHAP, the substrate for TPI, accumulates to high levels in TPI-deficient erythrocytes,[200] and the ATP concentration is usually low for cell age. These results indicate the presence of a substantial impairment in glycolysis in vivo. Reduction of residual TPI activity in deficient cells by binding to the red cell membrane or to brain microtubulin has been proposed to account for some of the differences between in vitro determinations of TPI activity and the evidence of a more severe impairment in enzyme function in vivo.[201-203] The defect can be partially bypassed by way of the HMP shunt, which generates glyceraldehyde 3-phosphate from glucose without the participation of TPI. Methylene blue stimulation of the shunt produces a lesser increase in glycolysis relative to baseline in TPI-deficient erythrocytes than in reticulocyte-rich control blood.[176] This has been interpreted as indicating a markedly greater "resting" shunt rate in the deficient cells, consistent with the proposed reliance of such cells on the shunt. Evidence indicates that TPI-deficient red cells are relatively deficient in antioxidant capabilities and that this deficiency may contribute to their shortened life span.[177,204]

Rare electrophoretic variants of TPI, not associated with reduced enzyme activity or hemolysis, have been described.[198,199,205,206] In anemic patients, enzyme kinetics and electrophoretic mobility are usually normal, but in vitro evidence of enzyme lability after heating is often obtained,[179-181,183] thus suggesting that instability and rapid loss of enzyme protein play an important role in the pathogenesis of hemolysis in vivo.[179,181] A single amino acid substitution (Glu→Asp) at position 104 has been identified in at least 17 geographically widely distributed families with clinically affected children and is the most commonly encountered mutation responsible for TPI deficiency.[185,190] Its relative rate of occurrence is thought to be the result of a founder effect. The Glu104→Asp TPI gene product is thermolabile.[207] Computer modeling indicates that a substituted amino acid at position 104, which is buried in a hydrophilic side pocket of the normal enzyme, will reduce the stability of the pocket, promote unfolding, and enhance thermolability.[207] Comparison of the recombinant mutant TPI enzyme to the recombinant wild type indicates that enzyme kinetics are normal but that dimer formation and thermal stability are greatly decreased. Analysis of the crystal structure of the mutant TPI suggests that a mutation-triggered disruption of the water network in the vicinity of the dimer–dimer interaction is the underlying basis for enzyme instability and ultimately for the clinical abnormalities.[208]

Fourteen TPI mutations have been defined.[185] Most clinically affected individuals are homozygous for a single mutation or compound heterozygous for two different mutations. In the Hungarian pedigree mentioned earlier,[193] a point mutation at codon 240 (Phe→Leu) produced a moderately thermolabile TPI with abnormal substrate kinetics and electrophoretic migration.[209] Phe240 is near the active site of the enzyme and appears to be essential for maintaining its correct geometry.[199] Furthermore, both anemic brothers in this pedigree inherited a nonsense mutation at codon 145 that terminated TPI protein synthesis, thereby producing a truncated protein and also reducing the output of TPI mRNA from the affected allele by 10- to 20-fold.[210] The red cells of the brothers had less than 10% of the TPI activity found in normal cells.[193,209]

The enzyme deficiency is manifested not only in red cells but also in leukocytes, platelets, muscle, serum, and cerebrospinal fluid. Histologic examination of muscle from a girl with TPI deficiency and myopathy revealed marked degenerative changes of the contractile system, altered mitochondria, and absent TPI by histochemical staining.[211] Brain and nerve tissue have not yet been analyzed, but the cerebrospinal fluid deficiency suggests that deficient TPI activity in neural tissue is responsible for the neurologic abnormalities observed in enzymopenic patients. Orosz and coworkers have advanced the hypothesis that mutant TPI is aggregation prone and that such aggregates might be neurotoxic, but direct evidence for this is not available.[191] Although increased susceptibility to infection might be the consequence of defective function by TPI-deficient leukocytes,[182] functional studies carried out on such cells in vitro have often been normal.[178,192] A functional defect in TPI-deficient platelets has been described.[212]

Genetics and Inheritance

Several large pedigrees display an autosomal recessive mode of inheritance of TPI deficiency.[178,181,185] Obligate heterozygotes are clinically normal, but their erythrocytes contain only approximately half the TPI activity of control erythrocytes. As is often the case in other glycolytic enzymopathies, no clear boundary exists between heterozygous deficient and low-normal enzyme activity. Several upstream polymorphisms are found at a high rate of occurrence in African-American populations.[185,213] Although they may be associated with mild reductions in erythrocyte TPI activity, they do not seem to be associated with clinical abnormalities, even in homozygotes.[185] At the other extreme, the homozygous state in mice for a TPI null allele is lethal early in embryogenesis.[214] A more informative mouse model results in an Asp→Gly substitution at codon 49 located in the functional domain of TPI. The mutant enzyme is highly thermolabile, resembling in this regard the human Glu104→Asp TPI mutant. Homozygous mice have only 13% of normal TPI activity and exhibit hemolytic anemia.[215] Simultaneous heterozygous inheritance of TPI deficiency and either G6PD deficiency or sickle cell trait has not altered the typical clinical pattern of the disorders when either is present alone.[177] TPI deficiency can be diagnosed prenatally by analysis of fetal blood cells,[184] cultured amniocytes,[183] or trophoblastic cells[189] with suitable precautions.[216] If the mutation is known, mutation analysis can be performed directly on fetal DNA.[189,210]

Therapy

Transfusions and folic acid supplementation are the therapies presently available. Splenectomy in one patient did not alter the intensity of hemolysis.[178] In vitro studies point to the possibility of transfer of TPI enzyme protein from normal to deficient cells with transient improvement in enzyme activity and a reduction in DHAP levels.[217] There have been no attempts to deliver normal TPI enzyme to patient tissues, but in other disease settings direct enzyme transfer from normal hematopoietic stem cell–derived microglial cells to enzyme-deficient nervous tissue after allogeneic stem cell transplantation has been successful.[217]

GLYCERALDEHYDE-3-PHOSPHATE DEHYDROGENASE DEFICIENCY

Clinical Manifestations, Biochemistry, and Genetics

Study of a large kindred in which three members exhibited a reduction in erythrocyte G3PD activity to 50% of normal levels yet were hematologically normal have clearly established that G3PD deficiency need not result in hemolysis.[218] The clinical severity of hemolytic anemia in four members of this pedigree who inherited both hereditary spherocytosis and G3PD deficiency was no greater than that associated with spherocytosis alone. Affected members of this kindred were presumed to be heterozygotes, because the amounts of both G3PD enzyme activity and enzyme protein were reduced equally to about 50% of normal and the amount of residual G3PD was qualitatively normal. Two of three patients who had anemia with G3PD deficiency in other kindreds had even lower levels of enzyme activity (20% to 30% of normal) and conceivably were either homozygotes or doubly heterozygous for two mutant G3PD genes.[219,220] However, as with the spherocytosis pedigree, a cause-and-effect relationship between hemolytic anemia and G3PD deficiency was not established.

PHOSPHOGLYCERATE KINASE DEFICIENCY

Clinical Manifestations

PGK deficiency is a sex-linked disorder that largely affects males. Nonspherocytic hemolytic anemia may occur alone or in combination with neurologic abnormalities ranging from emotional instability to seizures, movement disorders, psychomotor retardation, aphasia, or tetraplegia.[163,221] In a subset of individuals with PGK deficiency, myopathy is the dominant and sometimes the only clinical manifestation (Table 17-6). Individuals with one form of mild PGK deficiency (PGK München) exhibit no clinical abnormalities (see Table 17-6). In females, erythrocyte PGK activity is less depressed than it is in males, hemolytic anemia is mild or absent, and neurologic and muscle abnormalities are not seen (see Table 17-6).

Hematologic findings in individuals who have anemia with PGK deficiency have been those customarily associated with hemolysis, namely, jaundice and reticulocytosis. Hemolytic episodes are often associated with acute febrile illnesses. No changes in erythrocyte morphologic characteristics have been seen, and osmotic fragility has usually been normal.

Biochemistry

PGK is a monomeric enzyme with a primary structure consisting of 417 amino acids.[255] Horse and pig muscle PGK has a primary structure that is highly homologous to that of human PGK.[256,257] Crystallographic studies show that its tertiary structure consists of two lobes (the C and N domains) connected by a hingelike structure that allows considerable conformational change to occur during substrate binding (Fig. 17-4).[256,257] Because the nucleotide (adenosine diphosphate [ADP] and ATP) combining site is located within the C domain and the phosphoglycerate (1,3-BPG or 3-phosphoglyerate) binding site is within the N domain, bending of the enzyme is required to bring the several substrates required for the PGK reaction into close proximity.[257] Mutant PGKs often exhibit abnormal enzyme kinetics and diminished stability in vitro, properties that are likely to impair enzyme function in vivo (see Table 17-6).

PGK-deficient red cells are capable of normal glycolysis in vitro.[222,253] Intracellular ATP concentrations are normal or slightly low,[222,227,253] whereas the 2,3-BPG concentration is elevated, sometimes to two or three times the normal level.[208,213,218,223,237] These results reflect increased flow through the 2,3-BPG cycle (see Fig. 17-1) at the expense of the ATP-generating PGK reaction. Despite the availability of an alternative pathway (the Rapoport-Luebering shunt or the 2,3-BPG cycle) to bypass PGK, substantial accumulation of glycolytic intermediates proximal to the enzyme defect is found in fresh red cells, thus indicating that the normal flow of erythrocyte glycolysis is impeded in vivo.

Little is known about the mechanism of hemolysis of PGK-deficient red cells. Most PGK activity is membrane associated.[258] It has been suggested that the ATP for membrane adenosine triphosphatase (ATPase)–mediated cation transport is mostly (or entirely) generated by membrane-bound PGK. Indeed, ADP derived from membrane ATPase exerts an important regulatory influence on glycolysis by its participation in the PGK reaction.[259] However, the implication of a special role for PGK in cation transport has been challenged.[260] Active transport of Na^+ and K^+ by PGK-deficient red cells with residual PGK activity only 10% to 15% of normal was not impaired, even with the challenge of an increase in intracellular Na^+ concentration.[261] Thus it seems unlikely that hemolysis of PGK-deficient red cells is related to premature cation pump failure as a direct result of inadequate PGK activity.

PGK activity in leukocytes is consistently subnormal in affected males, but white cell function is not usually compromised.[233,262]

Genetics and Inheritance

The major structural gene for PGK, located on the long arm of the X chromosome, is 23 kb in size and composed of 11 exons and 10 introns.[263-266] PGK-deficient male hemizygotes demonstrate very little active enzyme and have more symptoms than heterozygous females do, who have higher levels of PGK activity (see Table 17-6). A second functional PGK gene, expressed only in spermatozoa, is found on chromosome 19.[267] This autosomal PGK gene lacks introns but is otherwise similar to the X-chromosomal PGK gene. A single isozyme of PGK is found in all human nonhematopoietic tissues except

spermatozoa.[268] It is therefore not surprising that nonerythroid tissues may be compromised in patients with erythrocyte PGK deficiency.

In 1972, Yoshida and coworkers[269] succeeded in purifying and sequencing both normal erythrocyte PGK and a clinically normal but electrophoretically distinct human mutant PGK, the New Guinea variant. The mutant enzyme differed from normal PGK by the substitution of arginine for threonine at position 352.[255] Subsequently, the structure of 17 other PGK mutants, most associated with clinical manifestations, has been determined by peptide or nucleotide sequencing (see Table 17-6). Fifteen of these mutants involve only a single amino acid (14 missense mutations and 1 deletion). The 16th activates a cryptic splice site that leads to the insertion of 10 additional amino acids into the PGK polypeptide, and the 17th, a 4-amino acid deletion, also affects splicing and produces a truncated polypeptide. The majority of the mutants are found within the C domain, as shown in Figure 17-4. It is not clear how the particular spectrum of clinical abnormalities associated with each mutation is related to its position within the molecule. For example, PGK Michigan, a point mutation at amino acid 316, is associated with hemolytic anemia and

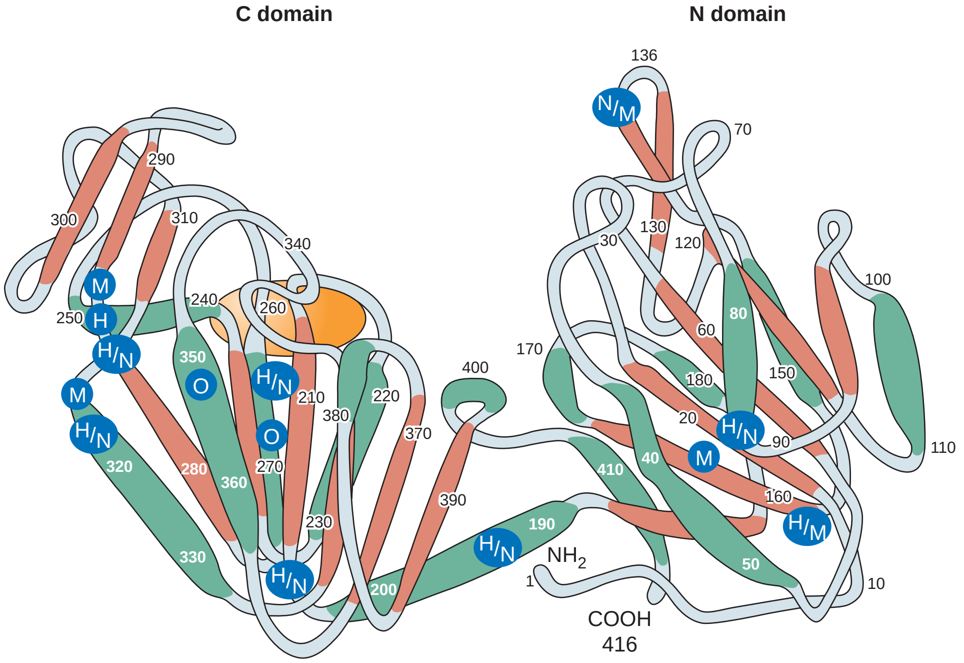

Figure 17-4 Three-dimensional model of human PGK. This figure is based on the three-dimensional model of horse PGK published by Banks et al.[256] Positions of the amino acid substitutions and the clinical features associated with 14 PGK point mutations are indicated by *filled circles*. The *orange shaded ellipse* in the C domain indicates the location of the ATP and ADP binding site. Random coil is *light blue*, β strands are *orange*, and α helices are *green*. *H*, Hemolytic anemia; *M*, muscle disease; *N*, neurologic manifestations; *O*, no clinical abnormalities. *(Modified from Fujii H, Kanno H, Hironi A, et al: A single amino acid substitution [157 Gly→Val] in a phosphoglycerate kinase variant [PGK Shizuoka] associated with chronic hemolysis and myoglobinuria.* Blood *79:1582–1585, 1992.)*

neurologic abnormalities, whereas individuals with PGK Creteil, a point mutation of the adjacent amino acid at position 315, do not have anemia and neurologic abnormalities but exhibit rhabdomyolysis.[270] Both mutants are thermolabile and demonstrate kinetic abnormalities in vitro, and both have similarly reduced activity in erythrocytes (see Table 17-6). Random inactivation of the mutant X chromosome may produce differing proportions of enzyme-deficient cells in female heterozygotes. Some may be anemic (see Table 17-6), whereas others are clinically and hematologically normal.[228] In the latter, the population of PGK-deficient red cells may be so small that erythrocyte PGK activity will be completely normal.[227]

Therapy

In one patient, splenectomy had no beneficial effect on anemia,[254] but in several others, surgery has decreased or eliminated the need for transfusions, reduced the degree of reticulocytosis, and sometimes resulted in an increase of several grams in the hemoglobin level.

2,3-BISPHOSPHOGLYCERATE MUTASE DEFICIENCY

Clinical Manifestations

Absence of erythrocyte BPGM activity does not affect red cell life span but may have other hematologic consequences. In one pedigree, four siblings who completely lacked functional red cell BPGM had polycythemia but were otherwise clinically and hematologically normal. All three children of these individuals had about 50% of the normal amount of red cell BPGM and were hematologically normal except for polycythemia.[271,272] In another patient with polycythemia, BPGM activity was only 4% of normal, 2,3-BPG was almost undetectable, and hemoglobin's oxygen affinity curve was shifted to the left. Despite the concomitant inheritance of severe erythrocyte G6PD deficiency, this individual did not have evidence of hemolytic anemia.[273]

Biochemistry

Human red cell BPGM is a homodimer whose identical subunits (relative molecular mass: 29,840) each consist of 258 amino acids.[274] Nearly all 2,3-BPG phosphatase activity also resides in the BPGM molecule, so 2,3-BPG metabolism is controlled by a single, multifunctional enzyme. In fact, purified BPGM is also capable of performing as an MPGM, though at a low rate of activity.[275] Considerable structural homology exists between red cell BPGM and MPGM,[276,277] and the enzymes to some extent exhibit overlapping functions. However, both biochemical[276] and genetic[278] evidence indicates that they are each unique and under separate genetic control.

The BPGM molecule has been modified in vitro by site-directed mutagenesis in an attempt to model a potential therapeutic approach to sickle cell disease.[279] Replacement of Gly13 by Arg enhances phosphatase activity at the expense of the mutase. The effect of such an alteration in vivo, achieved by gene therapy or by pharmacologic means, would be to lower erythrocyte 2,3-BPG levels, increase the affinity of hemoglobin for oxygen, and in this way retard the polymerization of hemoglobin S.

BPGM deficiency results in reduced synthesis of 2,3-BPG. In complete BPGM deficiency, there is virtually no 2,3-BPG within the red cell.[271-273] The affinity of whole blood for oxygen is increased because of lack of 2,3-BPG, thereby accounting for the polycythemia noted in individuals with BPGM deficiency.[271-273] The pattern of glycolytic intermediates is disturbed,[271] with a crossover at PFK sometimes being exhibited,[272] which is consistent with relief of the inhibitory influence of 2,3-BPG on PFK. The erythrocyte ATP concentration is usually normal or slightly increased, compatible with diversion of 2,3-BPG into the PGK reaction as a consequence of reduced flow through BPGM. Erythrocyte glycolysis and pentose phosphate pathway activity have been normal in vitro.[271] Probably as a consequence of the large amount of 1,3-BPG present in BPGM-deficient red cells, hemoglobin A may undergo posttranslational modification by glycerylation at a82. The modified hemoglobin, about 3% of the total, has a lower isoelectric-electric point than hemoglobin A_{1C} and is easily identified by isoelectric focusing.[280]

Genetics and Inheritance

The BPGM locus is on chromosome 7 (7q22-34).[281] The gene is fully expressed only in erythroid tissue.[272] BPGM deficiency has the expected autosomal recessive mode of inheritance.[271-273] Individuals from the large pedigree with polycythemia and virtually no red cell BPGM activity have been shown to be compound heterozygotes for two different BPGM mutations.[282] One, BPGM Creteil I, is a point mutation (Arg89→Cys) at or near the BPGM active site,[283] and the other, BPGM Creteil II, is a frameshift mutation caused by a deletion of nucleotide 205 or 206.[284] Only BPGM Creteil I enzyme protein is found in red cells.[285] It is catalytically inactive and thermolabile in vitro and exhibits altered electrophoretic mobility.[285] Although BPGM and 2,3-BPG phosphatase activity was virtually absent in compound heterozygotes, MPGM activity was nearly normal, thus illustrating the complex nature of this multifunctional enzyme.[283] The individual with severe BPGM and G6PD deficiency was homozygous for a missense mutation (*185*G→A*; Arg 62→Gln) in exon 2.[273]

Therapy

Polycythemia, if symptomatic, may require phlebotomy.[272]

MONOPHOSPHOGLYCERATE MUTASE DEFICIENCY

Clinical Manifestations, Biochemistry, Genetics, and Therapy

A woman with hereditary spherocytosis whose erythrocyte MPGM activity was reduced to about 50% of normal was found to have inherited two copies of a missense mutation (230met→isol) in the MPGM-BB isoenzyme, which is the form that contributes most of the MPGM activity in erythrocytes.[286] The mutant enzyme exhibited reduced thermal stability but normal kinetics.[287] Family members who inherited a single copy of the mutation were healthy, and no evidence was presented to indicate that in homozygotes MPGM deficiency influences the hemolysis associated with hereditary spherocytosis.[288]

ENOLASE DEFICIENCY

Clinical Manifestations, Biochemistry, Genetics, and Therapy

A woman in whom red cell enolase activity was only 6% of normal exhibited a modest reduction in the survival of ^{51}Cr-labeled autologous erythrocytes (half-life of 18 days; normal, 25 to 30 days) but no overt chronic anemia.[289] A severe, life-threatening acute hemolytic episode occurred when nitrofurantoin was administered for the treatment of a urinary tract infection. Enzymes of the HMP shunt all exhibited normal or increased activity, and glutathione stability was normal. Such drug-induced hemolysis is distinctly uncommon in disorders of the Embden-Meyerhof pathway, although it is theoretically possible in enzyme-deficient reticulocytes.[290] In this patient, in whom sudden massive hemolysis involved predominantly mature red cells, no biochemical mechanism has yet been defined, and the association between enolase deficiency and hemolytic anemia may be coincidental. A sister was hematologically normal, even though her red cells were as deficient in enolase activity as those of the propositus.

Partial red cell enolase deficiency was inherited in an autosomal dominant manner by six members of a second pedigree that spanned four generations. With the exception of the propositus, a 13-day-old boy with profound hemolytic anemia, affected family members were not anemic and had little or no evidence of hemolysis. Spherocytes were present on the peripheral blood smear, and the MCHC was usually elevated.[291]

A girl with Diamond-Blackfan anemia had near absent erythrocyte enolase activity pre–bone-marrow transplant with normal enolase activity 1 year after the transplant. Both parents also had subnormal erythrocyte enolase activity, but no hematological abnormalities. An autosomal recessive inheritance was suggested. The relationship, if any, between enolase deficiency and DBA was undefined.[292]

PYRUVATE KINASE DEFICIENCY

Clinical Manifestations

PK deficiency is the most commonly encountered glycolytic enzymopathy associated with anemia. Its incidence has been estimated to be 51 cases per million in white individuals.[293] Of the approximately 500 human patients thus far reported,[6,7] the majority have been of Northern European extraction. Sporadic instances have been seen in other ethnic groups. A hemolytic anemia resembling that seen in human PK deficiency has also been described in basenji dogs,[294,295] beagles,[296] cats,[297] and inbred mice[298] that inherited mutant forms of erythrocyte PK with subnormal activity. Anemia, jaundice, and splenomegaly are regularly present in PK deficiency. The anemia may be profound, occurring in utero[299,300] or in early infancy,[65] and require regular blood transfusions for survival. Conversely, the anemia may be mild enough to evade discovery until adulthood. In a few patients, anemia is absent, hemolysis is fully compensated for, and jaundice may be the sole clinical abnormality. When present, anemia is a lifelong condition and its intensity usually varies little, although it may become more severe during pregnancy.[301,302] Exacerbations of anemia are uncommon and generally result from transient erythroid hypoplasia after infections[303] or, rarely, from increased hemolysis of unknown cause. Iron overload is a common problem, particularly in adults. Transfusion, splenectomy, and coinheritance of hereditary hemochromatosis genes are factors that make iron overload more likely in PK deficiency.[304,305] Serum hepcidin levels are inappropriately low[306] or normal,[305] and ferritin levels are high,[306] indicating dysregulation of iron homeostasis, possibly related to ineffective erythropoiesis as is the case in the thalassemias. Iron chelation may be required.[304] Manifestations of PK deficiency outside the hematopoietic system are uncommon. In several pedigrees, chronic leg ulcers have been observed in family members with PK deficiency and hemolytic anemia.[307,308]

Hyperbilirubinemia is often encountered in newborns with PK deficiency,[309] and these infants may require exchange transfusions.[65] Serum unconjugated bilirubin levels remain elevated in later life, and gallstones are common. Unconjugated bilirubin levels greater than 6 mg/dL are occasionally seen[310]; one brother and sister regularly had levels greater than 20 mg/dL.[311] These patients have abnormal hepatic function in addition to hemolysis. Whether abnormalities in liver PK contribute to hyperbilirubinemia is unknown.[312,313]

Macrocytosis, occasional shrunken, spiculated erythrocytes, and rarely, acanthocytes may be observed on examination of the blood smear; these changes may be accentuated by splenectomy. More extreme alterations in erythrocyte morphologic characteristics are sometimes encountered (Fig. 17-5).[314,315] Such abnormalities in shape may result from the inadequate ATP synthesis characteristic of PK-deficient erythrocytes.[316] A paradoxical increase in the reticulocyte count often follows splenectomy despite evidence of a beneficial reduction in the rate of hemolysis. Reticulocyte counts may exceed 90%, and in many patients counts of 40% to 70% are maintained for years. Conversely, in other patients the expected reduction in reticulocyte count is seen after splenectomy. The osmotic fragility of fresh and incubated erythrocytes is most often normal, although minor populations of fragile or resistant cells may be encountered in occasional patients after incubation. The results of an autohemolysis test are generally, but not invariably[317] abnormal, with hemolysis of as many as 50% of erythrocytes after 48 hours of incubation in saline. Prior addition of glucose may reduce the hemolysis in some instances, but glucose usually has little or no effect. In fact, if the reticulocyte count exceeds 25%, incubation with glucose regularly accentuates the hemolysis. This phenomenon has been attributed to inhibition of oxidative phosphorylation by glucose (the Crabtree effect), with unfavorable consequences in PK-deficient reticulocytes because of their reliance on oxidative phosphorylation for synthesis of ATP.[318]

I. Morphology, erythrokinetics, and family enzyme studies.* N Engl J Med *270:1023–1030, 1964.)*

Biochemistry

The active form of PK is a tetramer formed from one of four different tissue-specific subunits. The R subunit is found in red cells; the L subunit in liver; the M1 subunit in muscle, heart, and brain; and the M2 subunit in all early fetal tissues and most adult tissues, including leukocytes and platelets.[319] The R and L subunits derive from a common gene (*PKLR*) located on chromosome 1 (1q21),[320] whereas the M1 and M2 subunits are generated by a second gene (*PKM*) located on chromosome 15 (15q22).[321] In the rat, the *PKM* gene is 20 kb long and consists of 12 exons and 11 introns.[322] M1- or M2-specific mRNA is formed from a common primary transcript by alternative spicing involving the removal of either exon 9 (M2) or exon 10 (M1).[323] Because human and rat M2 cDNA is highly homologous,[321] alternative splicing probably also accounts for the differences in M1 and M2 mRNA in humans. The *PKLR* gene also consists of 12 exons.[324] Tissue-specific expression of one of two different promoters generates a transcript containing either an R or an L exon at the 5′ end.[325,326] The remaining 10 exons are identical. L-type cDNA encodes a polypeptide of 543 amino acids,[325] whereas R-type cDNA encodes a product that is longer by 31 amino acids.[327]

The three-dimensional structure of cat and rabbit muscle PK has been studied by x-ray crystallography.[328] There is extensive sequence homology among species and between M and R subunits, particularly in the vicinity of the active site,[329] thus indicating that the enzyme structure has been conserved during evolution. Crystallographic analysis of recombinant human erythrocyte R-PK (Fig. 17-6) indicates a close homology to the three dimensional structure of muscle PK.[330] As shown in Figure 17-6, each PK subunit consists of a short aminoterminal region and three distinct domains (A, B, and C). Domain A is

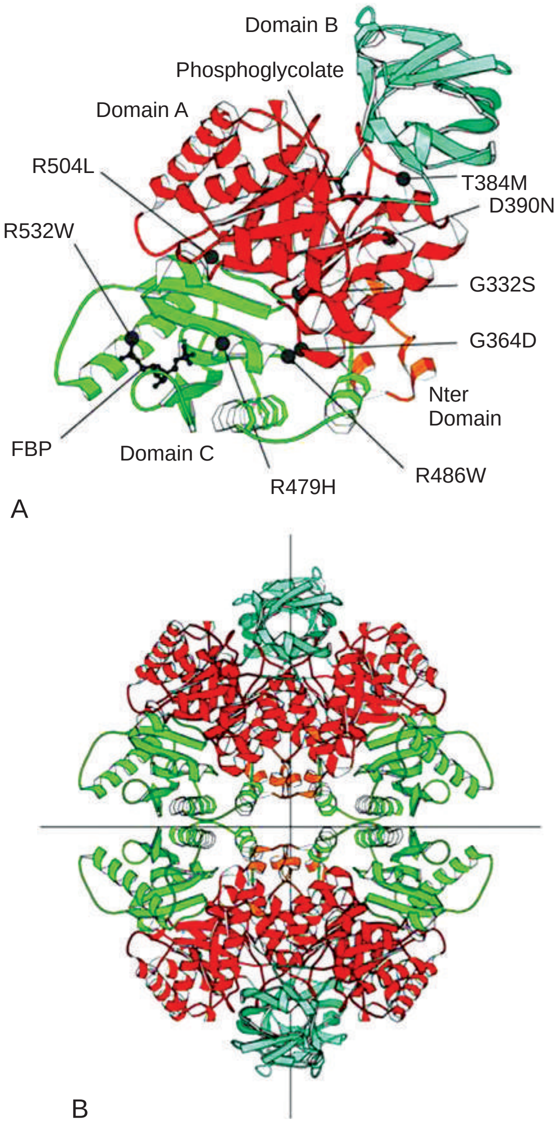

Figure 17-6 Three-dimensional crystal structure of erythrocyte PK (R-PK). The N-terminal domain is *orange,* the A domain is *red,* the B domain is *cyan,* and the C domain is *green.* The 49 N-terminal amino acids are not shown. **A,** Subunit structure. The active site lies in a pocket between domains A and B, the potassium and magnesium binding sites are in domain A, and allosteric modulation of PK function primarily involves interaction with domain C (the FDP binding site is indicated by *FBP*). Shown are the position of 8 mutations found in individuals with PK deficiency and hemolytic anemia *(gray spheres).* Analysis of recombinant enzyme proteins showed that 4 (G332S, G364D, R504L, and R532W) were associated with strongly perturbed kinetic and thermostability parameters as well as severe anemia. However, even enzymes (T384M) with only mild abnormalities in vitro could nevertheless be associated with a severe clinical phenotype, making predictions about the consequences of a particular mutation difficult. **B,** The RPK tetramer, formed of four identical RPK subunits. *(From Valentini G, Chiarelli LR, Fortin R, et al: Structure and function of human erythrocyte pyruvate kinase.* J Biol Chem *277:23807–23814, 2002.)*

cylindrical and formed by eight parallel strands of b sheet encased by an outer coaxial cylinder of eight a helices; domain B consists of a closed antiparallel b sheet; and domain C is a five-stranded b sheet connected by a helices. The active site lies in a pocket between domains A and B, the potassium and magnesium binding sites are in domain A, and allosteric modulation of PK function primarily involves interactions with domain C.

In erythroid cells, PK is a tetramer (relative molecular mass: 230,000[329]) with subunits that may vary in type. In erythroid precursors, M2 homotetramers are the predominant PK isoenzyme. With erythroid maturation, synthesis of M2 subunits declines and is replaced by production of R-type subunits.[331-333] The mature red cell enzyme may exist in either of two physical conformations, analogous to the R and T forms proposed by Monod and colleagues[334] for allosteric proteins. Partially purified enzyme preparations usually exhibit sigmoid kinetics in the presence of increasing concentrations of substrate (phosphoenolpyruvate). Small amounts of phosphoenolpyruvate facilitate further binding of substrate by the enzyme in a manner analogous to that seen with heme–heme interactions. Fructose 6-diphosphate (FDP) induces a transition from sigmoid to hyperbolic kinetics, probably by acting directly at the phosphoenolpyruvate binding site.[335]

A number of factors may result in posttranslational modification of the enzyme. Transition between an FDP-sensitive conformation with sigmoid kinetics and an insensitive form with hyperbolic kinetics has been achieved by varying pH,[336] temperature,[336,337] and conditions of storage. Aging of the enzyme in vivo appears to favor the FDP-sensitive conformation.[338] These transitions may play a significant role in modulation of PK activity in vivo. Posttranslational modification of enzyme properties mediated by oxidation of exposed thiol groups on the surface of the molecule may explain some abnormalities previously ascribed to genetic or acquired alterations in the primary structure of the enzyme.[338-343] In several instances it has been possible with the use of sulfhydryl reagents to restore to normal the altered stability and abnormal kinetics of mutant PK from individuals with hemolytic anemia.[339,344] On the other hand, it has often not been possible to implicate oxidation of enzyme thiol groups as a cause of abnormal enzyme properties.[345,346]

The enzyme is subject to numerous other regulatory influences. ATP is a competitive inhibitor ($K_i = 3.5 \times 10^{-4}$ mol/L)[347]; at physiologic ATP concentrations (approximately 1 mmol/L), erythrocyte PK activity should be significantly constrained by ATP. Both potassium[335,337] and magnesium[337,348] activate PK; rubidium (Rb^+) or ammonium (NH_4^+) substitute for potassium (K^+), and manganese (Mn^{2+}) or cobalt (Co^{2+}) can replace magnesium (Mg^{2+}).[341] Activation of purified PK by FDP has been demonstrated at concentrations normally found within the erythrocyte.[349] At a higher concentration (0.5 mmol/L), another glycolytic intermediate, G6PD, activates PK.[350] The glycolytic intermediate 2,3-BPG, of particular interest because of its high concentration in PK-deficient erythrocytes, has no influence on PK in hemolysates[351] but has variously been reported to inhibit[352] or activate[353] purified PK. Phosphorylation of PK, mediated by cyclic adenosine monophosphate, alters its kinetic properties and may regulate 2,3-BPG levels and thus oxygen transport by red cells.[353,354] It is clear that intracellular PK activity is determined by the complex interplay of a number of regulatory factors and may bear little relationship to measures of activity determined in vitro under optimal conditions.

When erythrocyte PK (R homotetramer) is abnormal, hepatic PK (L homotetramer) may also be affected because the R and L subunits are derived from a common gene. In two anemic individuals with PK deficiency, liver PK was reduced to 59%[355] and 46%[356] of normal. Residual liver PK, measured in the latter patient, was mostly of the M2 type. No disorders of hepatic function appear to result from such partial deficiency of PK.[357] In another individual, total liver PK activity was only 22% of normal, virtually no L-type enzyme was detectable, and there were abnormalities in serum aminotransferases.[312] Paradoxically, in still another individual, liver L-type PK exhibited entirely normal activity and properties despite abnormalities in the supposedly identical isoenzyme in the red cells.[313]

The metabolic capabilities of PK-deficient erythrocytes in vitro vary considerably. Although resting HMP shunt activity may be slightly to moderately low for cell age,[358] no significant effect on either oxidized or reduced glutathione (GSH) levels has been observed,[359,360] even after incubation with acetylphenylhydrazine.[359,361,362] However, results of the ascorbate cyanide test are abnormal in patients with PK deficiency, and stimulated HMP shunt activity is modestly depressed.[360] In many instances, glycolysis, as measured by the glucose consumption or lactate production of incubated erythrocytes, is markedly subnormal.[311,318,358] Such diminished glycolysis is relative rather than absolute because the glycolytic rate of enzymopenic cells can be increased substantially by incubation in a high-P_i medium.[318,363] A reduction of residual PK activity within the erythrocyte to 10% of normal still leaves sufficient enzyme to support normal glycolysis if potential enzyme activity is fully used. Such considerations indicate that intracellular regulators of PK function must play an important role in the reduced glycolysis characteristic of enzymopenic cells. Often, particularly with kinetic variants of PK, glycolytic rates characteristic of mature normal erythrocytes are achieved.[364-367] However, such rates are clearly subnormal in comparison to those attained by reticulocyte-rich control blood of an equivalent mean cell age.[364] Furthermore, the glucose consumption of incubated normal hemolysate is unchanged when supplemental purified PK is added, whereas the addition of supplemental PK to hemolysate from PK-deficient erythrocytes produces a substantial rise in glucose consumption.[364]

Accumulation of glycolytic intermediates proximal to the enzyme defect has customarily,[364,367] though not invariably,[364] been observed.[366] Detection of elevated 2,3-BPG or 3-phosphoglycerate levels in red cells may help confirm a clinical diagnosis of PK deficiency,[368,369] and the degree of elevation in 2,3-BPG or glucose 6-phosphate levels is directly correlated with clinical severity.[107,370] An alteration in the normal ratio of reduced nicotinamide adenine dinucleotide (NADH) to nicotinamide adenine dinucleotide (NAD), as well as complex changes in the substrates governing the rate of PK and 2,3-BPG mutase, appears to be responsible for triose phosphate accumulation when glycolysis is accelerated by P_i in normal red cells.[371] Such striking elevations in triose phosphate intermediates can be returned to normal in both control and PK-deficient red cells by the addition of exogenous pyruvate or another oxidant.[362] Concentrations of both NAD and NADH are low in PK-deficient erythrocytes,[357,372] or if the level of NAD is normal in fresh cells, it falls with undue rapidity on incubation in vitro.[363] The concentration of 2,3-BPG in PK-deficient erythrocytes may be greater than three times normal values, thereby leading to a rightward shift of the oxyhemoglobin dissociation curve.[52,53] The ability to extract a greater percentage of available oxygen from hemoglobin at any given pO_2 associated with such a right-shifted curve increases the exercise tolerance of patients with PK deficiency.[53] Such patients, though anemic, may exhibit none of the expected symptoms of fatigue and exercise intolerance.

The level of erythrocyte ATP and the formation of PRPP[373] are often abnormally low in PK deficiency, although patients with reticulocyte counts greater than 25% usually have normal ATP levels. In blood with such high reticulocyte counts, ATP is unstable on incubation with glucose, in contrast to normal reticulocyte-rich blood. When incubated without glucose, however, the PK-deficient reticulocyte conserves ATP more successfully than the normal cell does.[318] The reticulocyte, able to generate ATP from substrates other than glucose via oxidative phosphorylation, can circumvent its glycolytic defect. However, in a high-glucose environment, ATP levels plummet. The PK-deficient reticulocyte is thus exquisitely dependent on oxidative phosphorylation for maintenance of ATP, as was first shown by Keitt.[318] The greater oxygen consumption of PK-deficient reticulocytes than normal reticulocytes (3.75 ± 1.55 versus 0.56 ± 0.5 mL of $O_2/10^9$ reticulocytes/hr[312]) underscores the reliance of such cells on oxidative phosphorylation. Reticulocyte oxygen consumption is abolished by hypoxia in vitro at approximately venous pO_2 levels (Fig. 17-7). Therefore, when exposed to prolonged periods of hypoxia in vivo or on maturation with consequent loss of mitochondria, the PK-deficient immature erythrocyte becomes reliant on its inadequate glycolytic apparatus, with loss of cell ATP being the inevitable consequence. In contrast, the reduced ATP needs of the mature erythrocyte may be marginally, but adequately served for a time by the diminished glycolytic activity of the PK-deficient cell.

ATP depletion greatly increases the cation permeability of PK-deficient erythrocytes.[311] In part, this is the consequence of failure of the ouabain-inhibitable ATPase cation pump, which transports approximately 1 to 2 mEq of K^+ per hour per liter of erythrocytes.[374] Although adequate membrane ATPase is present,[364,375] a net loss of 0.2 to 6.3 mEq of K^+ per hour per liter of cells occurs in freshly obtained PK-deficient blood.[316,364,374] After ATP depletion, net K^+ loss may exceed 20 mEq/hr/L of cells.[311] Failure of the cation pump cannot explain such large losses of K^+. The effect of ATP depletion on K^+ permeability, first described by Gardos and Straub,[376] is a feature of all metabolically depleted red cells and is not unique

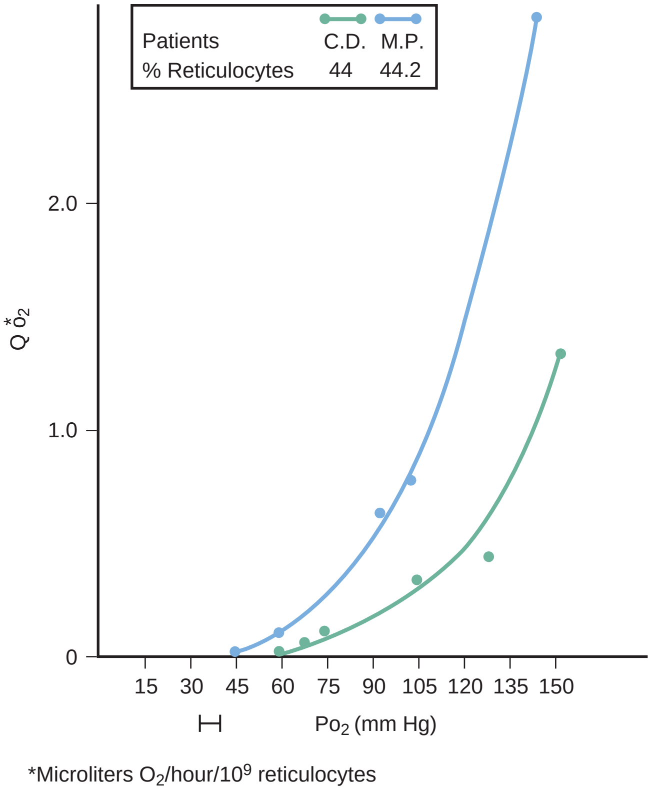

Figure 17-7 Influence of pO_2 on oxygen consumption by PK-deficient reticulocytes. The normal range for venous pO_2 is indicated by the *solid bar*. *(From Mentzer WC, Baehner RL, Schmidt-Schonbein H, et al: Selective reticulocyte destruction in erythrocyte pyruvate kinase deficiency.* J Clin Invest *50:688–699, 1971.)*

to PK deficiency. It is thought to be related to altered binding of membrane-associated Ca^{2+} and can be partially prevented by ethylenediaminetetraacetic acid or quinine, even though these agents have no direct influence on the rate or extent of ATP depletion.[311,377]

Initially in the ATP-depleted cell, potassium loss exceeds sodium gain. The resultant net loss of cations is accompanied by an obligate osmotic loss of water and a reduction in cell volume. The shrunken, crenated cells produced by ATP depletion in PK-deficient reticulocytes are shown in Figure 17-8. These spiculated cells pass, with difficulty, through 8-mm Millipore filters, and cell suspensions demonstrate increased viscosity in the Wells-Brookfield viscometer.[311] The destiny of such ATP-depleted erythrocytes, then, is to become dehydrated, rigid “desicytes” or “xerocytes,” with unfavorable characteristics that may well prematurely terminate their existence.[378] Membranes prepared from PK-deficient or normal ATP-depleted red cells are more dense than normal as a result of absorption of cytoplasmic components—in particular, an as yet unidentified 50,000-dalton protein—on the inner membrane surface.[379] Such changes in the cell membrane may contribute to the increased rigidity of these cells. There is evidence that membrane abnormalities not related to ATP depletion may also exist in PK-deficient red cells, but the role, if any, of such abnormalities in the hemolytic process is not established.[380] Not all workers have found abnormalities in the red cell membrane protein profile on sodium dodecyl sulfate–polyacrylamide gel electrophoresis,[381] and results of several other types of membrane analyses (spectrin extractability and membrane fluidity) have been normal.[382]

As enzyme-deficient erythrocytes age, a progressive reduction in glycolysis should accompany the inevitable gradual degradation of enzyme protein. Such deteriorating glycolysis eventually results in ATP depletion and subsequently, hemolysis. However, centrifuge studies have not revealed dramatic differences in the PK activity of enzymopenic young and old cells,[311] with the exception of one unstable PK variant[383] in which accelerated denaturation of enzyme protein was present in vivo, as well as in vitro. Deterioration in catalytic efficiency, reported to occur in both normal[338] and variant[384] enzymes on aging in vivo, may also hasten the demise of enzymopenic cells.

The normal or nearly normal survival of radiolabeled, severely PK-deficient erythrocytes reported by several investigators[311,365,366] indicates that diminished PK activity need not significantly curtail the life span of affected erythrocytes. Biphasic erythrocyte survival curves are sometimes obtained[385,386] and suggest that two populations of cells are present, one destined for almost immediate destruction and the other having a considerably better outlook for survival. Ferrokinetic studies[311,386] indicate that destruction of newly made erythrocytes in the bone marrow, spleen, or liver may be the major source of hemolysis in this disorder. Organ monitoring has shown that as reticulocytes are released from the marrow, some are almost immediately sequestered in the spleen. The paradoxical reticulocytosis that follows splenectomy is

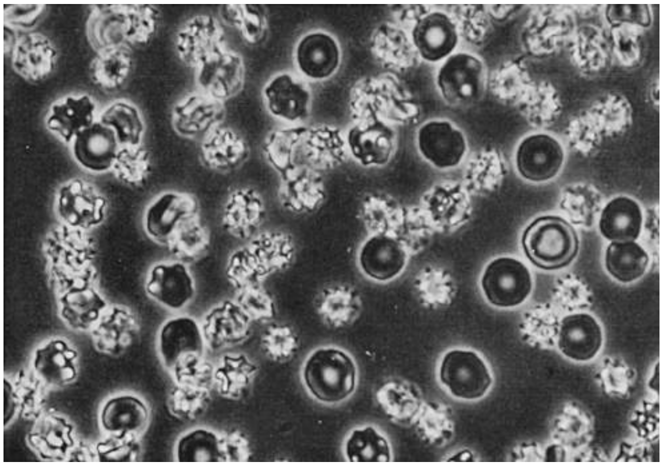

Figure 17-8 Phase-contrast micrograph of PK-deficient blood (patient C.D., whose anemia was severe after a 2-hour exposure to 5 mmol/L of cyanide to deplete ATP). The spiculated cells are, for the most part, reticulocytes (magnification ×6600). *(From Mentzer WC, Baehner RL, Schmidt-Schonbein H, et al: Selective reticulocyte destruction in erythrocyte pyruvate kinase deficiency.* J Clin Invest *50:688–699, 1971.)*

probably the consequence of improved survival of this population of reticulocytes.

Spleens removed from patients who have anemia with PK deficiency contain an unduly large number of reticulocytes.[361,387] Splenic histologic analysis shows the following results that contrast with those seen in hereditary spherocytosis: 1) the pulp spaces are empty rather than packed with erythrocytes; 2) erythrophagocytosis of reticulocytes and mature red cells by reticuloendothelial histiocytes is prominent in PK deficiency but rare in spherocytosis; and 3) many more crenated, deformed cells are seen in PK deficiency.[387,388] Studies of such cells obtained from peripheral blood have demonstrated them to be poorly deformable.[389] The hypoxic, acidic environment of the spleen would be expected to produce just such crenation in reticulocytes through the sequence of events outlined earlier: inhibition of oxidative phosphorylation, ATP depletion, selective K^+ leakage, loss of cell water, and resultant loss of cell volume. These rigid desicytes should negotiate the 3-mm fenestrations between the splenic cords and sinuses only with difficulty. Thus they are doomed to a stay of uncertain duration in the metabolically unfavorable splenic environment, and further deterioration in cell capabilities would seem inevitable. Isotope studies show that the final *coup de grace* often occurs in the liver.[390,391]

Splenic destruction of reticulocytes is a variable feature of PK deficiency; in some instances either bone marrow or liver destruction predominates. Why some reticulocytes are destroyed whereas others survive to reach maturity and thereafter have a nearly normal existence despite their enzyme defect is unclear. It is possible that chance determines which reticulocytes are detained in unfavorable metabolic circumstances. On the other hand, there is some evidence for actual variation in PK activity among reticulocytes.[311] Those with the most PK activity would be more likely to survive.

Although cellular dehydration has been given a central mechanistic role in the destruction of PK-deficient human red cells, it appears to be unimportant in the hemolytic process in PK-deficient basenji dogs. When PK-deficient dog red cells with high sodium levels are exposed to cyanide in vitro, they rapidly lose ATP. However, the ensuing loss of K^+ is balanced by an equivalent gain in Na^+, so no cellular dehydration occurs. Other mechanisms must explain the hemolysis in this setting.[390] Of possible interest in this regard is the finding of apoptosis of erythroid progenitors within the spleen of PK-deficient mice, thus suggesting a role for ineffective erythropoiesis in the anemia seen in this species[391] and perhaps in humans as well.[392]

Genetics and Inheritance

Autosomal recessive transmission of the enzyme defect is usually observed in PK deficiency. Homozygotes and compound heterozygotes exhibit hemolytic anemia. Simple heterozygotes can be distinguished from compound heterozygotes or homozygotes by the degree of reticulocytosis, the extent of accumulation of red cell glucose 6-phosphate, and the in vitro properties of the mutant PK.[393,394] Although simple heterozygotes usually remain clinically normal despite an approximately 50% reduction in erythrocyte PK activity, some may exhibit evidence of mild hemolysis.[394,395] Population surveys in different ethnic groups based on assays of red cell PK activity have estimated the incidence of PK heterozygosity to be 0.14% to 6%.[396-399,400,401] Because activity assays may sometimes falsely identify heterozygotes as normal and vice versa, DNA analysis should provide a more accurate estimate of the prevalence of PK mutations. A survey based on DNA analysis reported the rate of occurrence of heterozygosity in white individuals for the *C1456→T* mutation, the most common PK mutation in southern Europe, to be 3.5×10^{-3} and that for the *G1529A* mutation to be 2.03×10^{-3}. In African-Americans, the rate of occurrence of heterozygosity was 3.90×10^{-3} for the *C1456→T* mutation, and in Asians, it was 7.94×10^{-3} for the *C1468→T* mutation.[293] Evidence in PK-deficient mice with chronic hemolytic anemia suggests that PK deficiency may play a protective role against malaria.[402] In vitro studies with *Plasmodium falciparum*-infected red cells from human PK-deficient homozygotes and heterozygotes show reduced parasite invasion in homozygotes and preferential clearance of infected cells by macrophages in both homozygotes and heterozygotes. Using fluoride to inhibit enolase and reduce ATP levels in normal human erythrocytes, thereby simulating the metabolic defect that characterizes PK deficiency, a relationship was found between the degree of ATP depletion and reduced invasion by *P. falciparum* as well as enhanced clearance by macrophages. Thus a similar protective effect to that seen in mice, possibly mediated by ATP deficiency, may be present in humans.[399,403] Emerging population studies from malarial regions of Africa report a higher than expected incidence of PK deficiency, consistent with the hypothesis that, as in G6PD deficiency and sickle cell trait, PK heterozygotes are protected from malaria but confirmation requires much larger sample sizes.[404,405]

There is little correlation between the severity of anemia in homozygotes and the level of erythrocyte PK activity as measured by the conventional in vitro assay system,[406] unless enzyme activity is corrected for the degree of reticulocytosis present.[370] Variable clinical severity is explained, at least in part, by the existence of numerous mutant forms of the enzyme whose differing properties result in variable degrees of hemolysis. Mutants are distinguishable in vitro on the basis of maximal activity, electrophoretic mobility, substrate kinetics, stability, immunologic properties, and response to the activator FDP. In general, mutants with unfavorable kinetics are usually associated with more severe hemolysis.[370,407,408] Diminished thermal stability of the enzyme in vitro also seems important in determining clinical severity.[406] Homozygous frameshift, promoter, or deletion mutations that greatly reduce or completely abolish PK activity generally lead to such severe phonotypes as intrauterine death or life-threatening neonatal anemia, as does inheritance of a single copy of such deleterious mutations along with another severe PK gene.[409-413]

International standards for the characterization of mutant PK phenotypes have facilitated the comparison of mutants studied in different laboratories.[414] In compound heterozygotes, full characterization is difficult because tetramers formed from varying proportions of the two different mutant subunits are present, each with unique properties.[407] The best-defined phenotypes are those found in true homozygotes,[415] who are usually the offspring of consanguineous matings. The kinetic and electrophoretic abnormalities characteristic of each variant PK reflect underlying structural changes in the enzyme secondary to point mutations or deletions. A total of at least 190 mutations in the *PKLR* gene associated with chronic hemolytic anemia have been defined at the nucleic acid level,[406,413,415-418] Single-nucleotide missense mutations (including 2 in the promoter region) account for the majority of the total. The rest are splice site mutations, stop codon mutations, large and small deletions, frameshifts, or insertions. Additional PK mutations are known, but because they are present only as single copies in patients with chronic anemia, their role in the pathophysiology of hemolysis has not been defined.[406,416,417] In the basenji dog, PK deficiency is attributable to a frameshift mutation (deletion of C at nucleotide 433),[419] and in PK-deficient mice, a missense mutation in R-PK (338Gly→Asp) is responsible for the enzymopathy.[298] Most PK mutations are extremely rare and usually limited to a single family. Exceptions are the *G1529→A* and the *C1456→T* substitutions, common in European patients with PK deficiency,[406,420-423] and the *C1151→T* substitution, common in Japanese patients.[424] The majority of the mutations are located within exon 8 or 9 (A domain), where components of the active site and the K^+ binding site are located, or in exons 10 or 11 (C domain), a region responsible for the allosteric regulatory properties of the enzyme. Although important information about genotype–phenotype correlation has been developed,[370,406,413,425-427] detailed analysis of the way in which each mutation disturbs the function of PK and produces the clinical phenotype observed has only recently become available after ascertainment of the crystalline structure of human R-type PK and the use of recombinant ribose-phosphate pyrophosphokinase (RPPK) generated in *E. coli* to study enzyme kinetics and stability.[330,406,413,428] For example, generation of the *G1529→A* (510 Arg→Gln) mutant, the most common mutation found in northern Europe, by site-directed mutagenesis produced a recombinant enzyme with normal substrate kinetics and activation by FDP but with strikingly decreased stability.[428] These studies suggest that the hemolytic anemia seen in *G1529→A* homozygotes, which can be moderate to severe, is the result of low PK activity caused by enzyme instability in vivo rather than unfavorable enzyme kinetics. The variable clinical severity seen in different *G1529→A* homozygotes remains unexplained by these molecular studies and suggests a role for epigenetic or environmental factors.[406,413] DNA analysis has indicated that several PK variants thought to be unique because of differing enzyme properties are in fact caused by a single shared mutation. For example PK Maebashi, PK Fukushima, and PK Sendai are each the consequence of a substitution of A for C at nucleotide *1261*.[406] DNA analysis has also made possible the prenatal diagnosis of PK-deficient fetuses.[429]

When kinetic abnormalities have been discovered in anemic patients, at least one parent has exhibited similar abnormalities. The other parent may also have kinetically aberrant PK[430] or is found to have a low-activity variant with normal kinetics.[431] Occasionally, it has not been possible to demonstrate an abnormality of erythrocyte PK in one[416] or both[383] parents of patients with PK activity in the homozygous deficient range. Staal and coworkers[383] have speculated that in some heterozygotes, a compensatory increase in synthesis of enzyme protein by the normal allele may result in enzyme activity indistinguishable from normal. The "classic" form of PK deficiency is associated with severe enzyme deficiency, persistence of the M2 isoenzyme in mature erythrocytes, and little or no R isozymes. The persistence of M2 isoenzyme may represent an attempt to compensate for the lack of R subunit–containing forms of PK.[315] An analogy to the persistence of fetal hemoglobin synthesis in β-thalassemia has been made by Miwa.[432] When M2 compensation is incomplete or absent,[411] PK activity in mature red cells is low and hemolytic anemia ensues. When M2 isoenzyme is synthesized at a higher rate, greater than normal amounts of PK activity can accumulate in mature red cells.[333,433-436] Such patients do not have hemolytic anemia, and in fact the increased glycolytic flow through PK at the expense of the 2,3-BPG–generating pathway may lower 2,3-BPG levels, increase the affinity of hemoglobin for oxygen, and result in erythrocytosis. Similarly, mice bearing a mutant form of R-type PK exhibit a delayed onset of hemolytic anemia after birth that coincides with delayed switching from the M2 isoenzyme to the mutant R isoenzyme.[437]

A kindred in which hemolytic anemia occurred in heterozygotes for PK mutants was studied by Etiemble and colleagues.[438] PK activity was well below the 50% activity (17% to 45%) usually encountered in the presence of one normal and one mutant PK allele. It was thought that perhaps the presence of only one mutant subunit in the PK tetramer might be sufficient to reduce its catalytic function, with greater impairment found in the presence of additional mutant subunits. Similar considerations were raised in another kindred (PK Greensboro), in which heterozygotes exhibited less than 50% of the normal red cell PK activity but no hemolytic anemia.[439] However, in neither kindred was the presence of multiple combinations of mutant and normal subunits (i.e., M4, M3N, M2N2, MN3, and N4, where M is the the mutant subunit and N is the normal subunit) actually confirmed.

To date no evidence suggests interaction between PK deficiency and most other disorders of the erythrocyte such as β-thalassemia minor,[440] band 3 deficiency,[441] or G6PD deficiency.[314] Markedly increased involvement of the kidneys was noted at autopsy in a patient with Gaucher disease who also exhibited hemolytic anemia and deficiency of erythrocyte PK. It was suggested that cerebroside production was enhanced as a result of hemolysis.[442] Several individuals who inherited both severe PK deficiency and sickle cell trait had symptoms suggestive of sickle cell disease, possibly related to changes in oxygen affinity associated with high 2,3-BPG levels.[443,444]

Therapy

Although complete cure is not achieved by splenectomy, elimination or amelioration of transfusion requirements, a decrease in bilirubin level, and an increase in hemoglobin concentration are seen quite often. Even though splenectomy may be lifesaving in individuals with severe anemia,[361,366] the procedure may have no effect in individuals with mild anemia. When significant morbidity exists, it would seem reasonable to recommend splenectomy, bearing in mind the fact that the degree of benefit cannot be predicted with certainty.[445] The results of therapeutic intervention with agents that either circumvent the metabolic aberrations induced by the defective enzyme or directly modify enzyme activity have generally been disappointing, although a recent abstract reports normalization of metabolic activity in red cells from PK deficient patients by a small molecule, AG-348.[344,383,446-448,449a]

Although hemolytic crises are uncommon in patients with PK deficiency and have not been associated with drug ingestion, Glader[290] demonstrated a potential hazard with the use of large doses of salicylate in patients with severe PK deficiency. Salicylates inhibit oxidative phosphorylation and thus cause ATP depletion and cellular dehydration in severely PK-deficient reticulocytes in vitro. The salicylate doses used by Glader were high but were equivalent to serum levels achieved with chronic salicylate therapy for disorders such as rheumatoid arthritis. It is prudent to select alternative therapy for such patients when possible or to monitor them carefully for signs of increased hemolysis.

Bone marrow transplantation has permanently corrected the hemolytic anemia seen in PK-deficient basenji dogs,[449] in PK-deficient mice,[450,451] and in a single human with PK deficiency.[452] The potential feasibility of gene therapy has been demonstrated in PK-deficient mice.[453,454,455]

LACTATE DEHYDROGENASE DEFICIENCY

Clinical Manifestations, Biochemistry, and Genetics

Partial or complete absence of the H subunit of lactate dehydrogenase (LDH) in erythrocytes, leukocytes, platelets, and serum is not associated with anemia or hemolysis.[456] M-subunit deficiency, though associated with exertional myoglobinuria and a characteristic skin eruption, also does not lead to hemolytic anemia.[457] In contrast to humans, mice homozygous for a low-activity mutation of the skeletal muscle subunit of LDH have less than 10% of normal enzyme activity in erythrocytes and exhibit severe lifelong hemolytic anemia.[458]

ABNORMALITIES OF ERYTHROCYTE NUCLEOTIDE METABOLISM

In individuals with CNSHA, low erythrocyte ATP levels often play a central role in the pathogenesis of hemolysis. Hemolytic anemia associated with an unusually high erythrocyte ATP level has also been described.[459] Red cell PK levels were normal in the affected pedigree, so the mechanism for ATP elevation would appear to differ from that found in other families with high red cell ATP levels, low 2,3-BPG, erythrocytosis, and a twofold or greater elevation in PK activity.[433-435] In yet another family, two infants with hemolytic anemia, high erythrocyte ATP levels, and low 2,3-BPG levels had reduced 2,3-BPG phosphatase activity.[460] The relationship of this enzyme abnormality to the unusual elevation in erythrocyte ATP level or to hemolysis is uncertain. In the three disorders of erythrocyte nucleotide metabolism to be described in the text that follows, evidence of a relationship between the abnormal enzyme and hemolytic anemia is more convincing, although even in these disorders much remains to be learned about the pathogenesis of hemolysis.

Pyrimidine 5′-Nucleotidase Deficiency

Clinical Manifestations

Deficiency of erythrocyte P-5′-N, the most common inherited abnormality of nucleotide metabolism causing hemolytic anemia, is associated with lifelong anemia of moderate severity.[10,461-470,471,472] Splenomegaly is usually present, and iron overload may occur in adults.[471] Developmental delay is sometimes seen, but whether it is a direct result of P-5′-N deficiency has not been determined. Pronounced basophilic stippling, which may occur in as many as 5% of all erythrocytes, is an important and useful finding and an exception to the usual lack of distinguishing morphologic abnormalities in erythroenzymopathies. Definitive diagnosis requires assay of red cell P-5′-N activity.

Biochemistry

Reticulocyte maturation requires disposition of intraerythrocytic ribosomal RNA, which is no longer required for protein synthesis. The hydrolysis of pyrimidine nucleotides (cytidine monophosphate [CMP] and uridine monophosphate [UMP]) formed by the action of ribonucleases on ribosomal RNA, an essential step in RNA degradation, is catalyzed by P-5′-N. The cytidine and uridine formed can diffuse across the cell membrane, whereas the pyrimidine nucleotide substrates of the nucleotidase reaction are incapable of diffusion and accumulate within the cell when activity of the nucleotidase is subnormal.[10]

Hirono and associates[473] found two different isoenzymes of P-5′-N in hemolysates from normal subjects and those with P-5′-N deficiency. Only one isoenzyme, CMP responsive, was deficient in all five subjects evaluated with P-5′-N deficiency, whereas the other, deoxythymidine monophosphate (dTMP) responsive, was normal. Kinetic and thermostability abnormalities were seen in the CMP-responsive isoenzyme from subjects with P-5′-N deficiency but not in the dTMP-responsive isoenzyme. Apparently, the lack of overlapping substrate sensitivities makes it impossible for the residual normal isoenzyme to substitute for its deficient partner in enzymopenic individuals.

The amount of nucleotides in P-5′-N–deficient red cells is increased by 1.3 to 5.0 times, chiefly as a result of an increase in pyrimidine derivatives (CMP, cytidine diphosphate [CDP], cytidine triphosphate [CTP], UMP, uridine diphosphate, and uridine triphosphate [UTP]).[10,463,464,474,475] The most abundant derivatives are the diphosphodiesters CDP-choline and CDP-ethanolamine.[473] Accumulation of pyrimidine derivatives is undoubtedly caused in part by RNA degradation,[464] but it may also reflect de novo synthesis of these compounds from the uridine and orotate transported into the red cell.[476] Classification of P-5′-N deficiency as a high-ATP syndrome was based on early observations of unusually high ATP levels in cells, as measured with an enzymatic assay of ATP content that also reflected the presence of other nucleotide triphosphates, notably CTP and UTP. More specific assays have subsequently shown that cell adenine nucleotide levels are normal or even low rather than elevated.[10,465,475]

The extraordinary accumulation of pyrimidine nucleotides within P-5′-N–deficient red cells is easily detected by subjecting cellular extracts to MRI[477] or to ultraviolet spectroscopy. Extracts from normal cells exhibit an absorbance peak at 255 to 260 nm (caused almost entirely by the presence of adenine nucleotides). In P-5′-N deficiency, a higher absorbance peak slightly shifted in position (266 to 270 nm) is observed as a result of the presence of large amounts of pyrimidine nucleotides and provides a relatively simple means of screening patients for the disorder.[10,464] Measurement of inorganic phosphorus liberated from uridine monophosphate by P-5′-N is an equally simple approach to screening.[478] The secondary effects of P-5′-N deficiency are complex. For example, the concentration of GSH is regularly increased by a factor of 1.5 to 2.3,[468] a finding that may help confirm the diagnosis in patients suspected of having P-5′-N deficiency. Red cell PRPP synthetase activity is markedly low (15% to 35% of normal) in P-5′-N–deficient red cells.[479,480] In fact, PRPP synthetase deficiency was originally thought to be the primary defect responsible for the hemolysis. It is now regarded as a secondary phenomenon.[470] Pyrimidine nucleotides have been shown to bind and sequester magnesium, a cofactor required for subunit aggregation and maximal activation of PRPP synthetase.[481] Magnesium depletion (by the addition of pyrimidine nucleotides) also inhibits PK and pentose phosphate pathway activity in hemolysates. On the other hand, red cell magnesium levels are normal or even elevated in P-5′-N–deficient red cells, and incubation of these cells with exogenous magnesium does not reduce their susceptibility to autohemolysis or to Heinz body formation.[482] The role of magnesium deficiency (or unavailability) in the central abnormalities that limit the life span of P-5′-N–deficient red cells is not clear.

In fact, it is not known why P-5′-N–deficient red cells are destroyed prematurely. Perhaps the pyrimidine nucleotides that accumulate interfere with the normal function of key glycolytic enzymes by competing for available binding sites with the adenine nucleotides that are the normal enzyme substrate. The possible importance of pyrimidine nucleotides in hemolysis is underscored by the report of an individual with chronic hemolysis, basophilic stippling, and normal P-5′-N activity, in whom the only biochemical abnormality detected was a striking elevation in erythrocyte CDP-choline.[483] Accumulation of pyrimidine nucleotide has been shown to lower red cell pH in P-5′-N–deficient red cells as a result of shifts in Donnan equilibrium caused by the increase in fixed intracellular anion.[468,474] This drop of 0.1 to 0.2 pH unit is sufficient to increase the red cell's oxygen affinity above the normal range[475] and may also explain the slightly subnormal glycolytic rate of P-5′-N–deficient red cells.[484] Tomoda and colleagues[435] demonstrated a moderate impairment in stimulated pentose phosphate pathway activity in P-5′-N–deficient erythrocytes, which they attributed to inhibition of G6PD by pyrimidine nucleotides. This impairment in shunt activity is noted in both light and dense red cells separated by centrifugation and is accompanied by a parallel decrease in G6PD activity.[485] It is hard to visualize how pentose phosphate pathway failure could result in the unusually high levels of GSH characteristic of P-5′-N deficiency because the opposite effect, a deficiency in GSH, would be predicted.[468]

Study of individuals with lead poisoning has confirmed the central role of P-5′-N deficiency in the origin of hemolytic anemia. P-5′-N is markedly inhibited in vitro by low concentrations of lead, and the red cells of patients with significant lead poisoning have depressed levels of P-5′-N activity.[486] The basophilic stippling that is present in some patients with lead poisoning has been attributed to nucleotidase deficiency.[487] Although accumulation of pyrimidine nucleotides within erythrocytes is not found in all patients with lead poisoning in which P-5′-N activity is reduced, it is regularly found in patients exhibiting acute lead-induced hemolytic anemia.[486,487] Perhaps because of the shorter duration or less severe character of the enzyme deficiency, the red cells of lead-poisoned individuals do not exhibit RPPK deficiency.[487] GSH levels are normal[487] or elevated.[464] Despite the less-than-perfect homology between congenital and acquired P-5′-N deficiency, study of the latter may be expected to provide important insight into the mechanisms of hemolysis in this disorder.

Genetics and Inheritance

The gene for P-5′-N is located on chromosome 7 and consists of 11 exons. Alternative splicing leads to the production of three proteins: one is 286 amino acids long (P-5′-N I), the second is 297 amino acids long, and the third, found only in reticulocytes, is 285 amino acids long.[488,489] P-5′-N I is the major isoenzyme expressed in erythrocytes. Twenty-seven different mutations in P-5′-N I have been identified in patients with P-5′-N deficiency and chronic hemolytic anemia.[472] Nine are missense mutations, two are in-frame deletions that lead to loss of a single amino acid, and the remaining 16 are nonsense mutations, splice site alterations, insertions, or larger deletions.[471]

Approximately 100 patients with P-5′-N deficiency and hemolytic anemia have been described.[470-472,490] The disorder has been found in many ethnic groups.[471] Inheritance is autosomal recessive.[464,471] Nearly all patients who have P-5′-N deficiency and exhibit hemolytic anemia are homozygous for a single P-5′-N mutation; the remainder are compound heterozygotes for two different mutations.[471] Heterozygotes have no clinical manifestations but exhibit a reduction of about 50% in red cell P-5′-N activity.[10,464,470,471] The wide range of enzyme activity encountered in normal individuals makes detection of heterozygotes difficult in some families.[491] Variation in the severity of disease is, in part, the result of heterogeneity in the molecular nature of the defective enzyme.[462,473,492] This has been shown most clearly by study of the biochemical properties of purified recombinant mutant P-5′-N.[472,493] These studies also revealed that despite profound abnormalities in P-5′-N kinetics or stability in vitro, erythrocytes containing certain P-5′-N mutations exhibited only a moderated reduction in P-5′-N activity, thus suggesting that other pathways or other P-5′-N isoenzymes could compensate for P-5′-N I deficiency. P-5′-N has been found in the spleen,[492] kidney, and brain.[494,495] The presence of the enzyme in the brain may be relevant to the mental retardation noted in several individuals who have P-5′-N deficiency with hemolytic anemia.[465]

Therapy

The congenital form of P-5′-N deficiency must be distinguished from the acquired form associated with lead poisoning because specific therapy is available for the latter. The benefit of splenectomy in congenital P-5′-N deficiency is limited.[470] Investigational therapeutic use of allopurinol in one affected individual had no effect on hemolysis and actually increased erythrocyte pyrimidine nucleotide levels.[476]

Adenylate Kinase Deficiency

Clinical Manifestations, Biochemistry, and Genetics

Controversy exists regarding the exact role of adenylate kinase (AK) deficiency in hemolytic anemia. Beutler and colleagues[496] studied two African-American siblings whose red cells lacked measurable AK activity. One had hemolytic anemia, but the other did not. It was suggested that in this family the hemolysis was unrelated to AK deficiency or that another coexistent defect was required for hemolysis to occur. The latter seemed to be the case in an Arab family in which two siblings had severe red cell AK deficiency but only the sibling who had also inherited severe G6PD deficiency exhibited hemolysis.[497] However, further investigation of this large pedigree disclosed six more individuals with severe AK deficiency and mental retardation.[498] All had chronic nonspherocytic hemolytic anemia. Three had also inherited G6PD deficiency and were severely anemic, with red cell transfusions required 6 to 10 times annually. The other three, who did not have G6PD deficiency, were moderately anemic and only occasionally required transfusions. Family members who had carrier levels of red cell AK activity (50% of normal), either with or without G6PD deficiency, and individuals with G6PD deficiency alone did not have chronic hemolytic anemia. These results suggest that either AK deficiency has a direct role in hemolysis or the enzyme defect is a marker for another genetically linked but as yet unidentified defect that is the primary cause of the anemia.[499] Lachant and colleagues[499] found no AK activity in the red cells of a Syrian girl who had chronic hemolytic anemia. Only modest impairment in the formation of ADP from adenosine monophosphate was observed in intact cells, thus suggesting that alternative pathways might be available to substitute for the missing AK. Alternatively, it was proposed that AK itself might be present in intact cells but somehow became inactivated during preparation of a hemolysate for assay of enzyme activity. Eight additional patients with AK deficiency associated with hemolytic anemia have been reported in France,[500] Japan,[501,502] Spain,[503] and Italy.[504-506] Molecular study of these patients has defined three missense, two in-frame single-codon, and two nonsense mutations. Site-directed mutagenesis of wild type AK1 cDNA followed by expression of mutant enzyme proteins in an *E. coli* system and purification of enzyme protein allowed characterization of five of these mutations. Marked abnormalities in enzyme stability and catalytic properties were found.[507] Modeling studies using the structure of porcine AK, which is highly homologous to human AK, have begun to define the structural basis for mutation-associated defects in enzyme function.[503] The Japanese subject inherited a missense mutation (Arg128→Trp) in the coding region of the *AK1* gene from her mother and a normal *AK1* allele from her father. Although both mother and child were heterozygous for AK deficiency, only the child exhibited hemolytic anemia, and the mother was hematologically normal.[502] An Italian girl homozygous for a missense mutation at codon 164 had virtually undetectable erythrocyte AK activity and moderate hemolytic anemia.[504,505] Another Italian girl, who also had moderate hemolytic anemia, was homozygous for a deletion that created a frameshift with a premature stop codon. Even though no erythrocyte AK mRNA was detectable, thus implying rapid degradation of the truncated mRNA, a low level of AK enzyme activity was present in hemolysates from the propositus. Evidence of activity of other AK isozymes, not usually present in erythrocytes, was obtained, and this residual AK activity was thought to have mitigated the clinical severity of the enzymopathy.[506] Two siblings in a third Italian family who were homozygous for a nonsense mutation at codon 107 (*CGA*→*TGA*) had no detectable erythrocyte AK activity and mild to moderate chronic hemolytic anemia.[505] Both siblings also exhibited psychomotor retardation. Similar findings in other families[498,500] suggest that AK deficiency may be shared by the red cell and the brain.

Therapy

Splenectomy led to prompt disappearance of anemia and hemolysis in five of six Arab patients.[498]

Adenosine Deaminase Overproduction

Clinical Manifestations, Biochemistry, and Genetics

Fourteen individuals in three families have been found to have hereditary hemolytic anemia, sharply diminished amounts of intraerythrocytic adenosine nucleotides (to less than 50% of normal), and a remarkable 45- to 110-fold increase in red cell ADA activity.[508-511] In contrast to virtually all other erythroenzymopathies, ADA excess is transmitted as an autosomal dominant trait. Hemolysis is apparently the consequence of diminished red cell

ATP content, which is caused by the diversion of nearly all adenosine metabolism through the unusually active ADA reaction at the expense of the competing adenosine kinase reaction. The former results in irreversible loss of adenosine nucleotides, whereas the latter conserves such nucleotides and preserves cell ATP stores. The finding of abnormalities of lesser magnitude in other enzymes of nucleotide metabolism in affected individuals suggests that the excess ADA activity may be caused by an as yet undefined primary defect. The physical properties of the mutant ADA are normal,[510,512] which indicates that the great excess of ADA activity is caused by overproduction rather than an increase in catalytic efficiency. In one subject, an increase in red cell ADA protein equivalent to the striking increase in ADA activity was demonstrated by immunoblotting.[513] Synthesis of ADA by erythroid progenitors grown from bone marrow cells was 11-fold greater in an affected individual.[514] Ribonuclease (RNase) mapping techniques and Northern blotting have revealed at least a 100-fold increase over normal in the ADA mRNA content of affected reticulocytes. Sequencing of ADA cDNA showed no abnormalities in the coding region and 5′- and 3′-untranslated regions of the parent mRNA. Examination of genomic DNA by Southern blotting did not disclose evidence of gene amplification, deletion, or gross rearrangements. Thus although the basis for ADA excess appears to be an overabundance of apparently normal mRNA, the mechanism underlying this abnormality remains obscure.[515-517] Much lower increases in ADA activity (approximately fourfold) are seen in congenital hypoplastic anemia,[518,519] arthrogryposis multiplex congenita,[520] acquired immunodeficiency syndrome,[521] and cartilage-hair hypoplasia.[522] The origin and implications of these increases are obscure, but they are not associated with hemolysis.

ACQUIRED DISORDERS OF ERYTHROCYTE GLYCOLYSIS

Alterations in the external chemical milieu may profoundly influence erythrocyte metabolism. The rate of glycolysis, for example, is governed by the availability of P_i. High concentrations of P_i augment and low concentrations impede the glycolytic synthesis of ATP and 2,3-BPG. Erythrocytes from uremic patients with hyperphosphatemia contain an average of 70% more ATP than normal erythrocytes do, and a lesser but significant increase in 2,3-BPG concentration is also found in the hyperphosphatemic cell.[523] Conversely, hypophosphatemia is associated with a reduction in erythrocyte organic phosphates. Red cell glucose metabolism is compromised in patients with severe hypophosphatemia (serum phosphorus level less than 0 to 0.3 mg/dL).[523-525]ATP and BPG levels decline and hemoglobin oxygen affinity increases.[526,527] If the red cell ATP concentration falls to very low levels (10% to 20% of normal), a severe hemolytic anemia characterized by marked microspherocytosis, spheroacanthocytosis, and red cell rigidity results[525,528-530] Hemolysis is reversible after phosphate repletion and ATP regeneration. Severe hypophosphatemia can occur with gastrointestinal malabsorption, use of phosphate binders,[528] starvation, diabetes mellitus, increased urinary losses resulting from tubular dysfunction, hyperalimentation with low-phosphate nutrients,[524] and after nutritional repletion (e.g., refeeding in anorexia nervosa[531] or in severe malnutrition[532]).

Some investigators have found that experimental magnesium deficiency in the rat resembles hypophosphatemia in that erythrocyte glycolysis is inhibited, ATP and 2,3-BPG levels are subnormal, and red cell rigidity is increased. Spherocytes are evident on the blood smear, and red cell survival is reduced.[533] Magnesium is essential for the normal function of a variety of glycolytic and nonglycolytic enzymes. However, using a different diet to induce magnesium deficiency, Piomelli and coworkers[534] showed that although hemolytic anemia accompanies magnesium depletion in rats, erythrocyte glycolysis and the activity of red cell glycolytic enzymes remain normal. Magnesium deficiency also influences other red cell components, notably the membrane,[535] and the relative contribution of such abnormalities to shortened red cell life span remains undefined.

Iron deficiency not only decreases the production of red cells but also accelerates their destruction.[536] Studies of the metabolic properties of iron-deficient red cells have revealed several abnormalities that might reduce cell viability. Although erythrocyte glycolysis in vitro is normal for cell age,[537] cell ATP is unstable on incubation. The ATP concentration in freshly obtained red cells may be either normal[538] or low.[539] The spontaneous autohemolysis of iron-deficient red cells incubated at 37° C is increased.[540] The increased rigidity characteristic of an ATP-depleted cell is present in iron-deficient cells as well.[540] These findings suggest that a defect in energy metabolism may contribute to the shortened survival of iron-deficient red cells.

Alterations in erythrocyte enzyme activity are often found during the course of either acute or chronic leukemia,[541] nonmalignant pancytopenia,[541,542] congenital dyserythropoietic anemia,[543] acquired dyserythropoietic anemia,[541,544] myeloid metaplasia,[541] and polycythemia vera.[541] One, several, or many enzymes may be involved, and activity may be either increased or decreased. The unusual pattern of enzyme activity may, on occasion, be useful in diagnosis, for example, to distinguish congenital hypoplastic anemia from transient erythroblastopenia of childhood.[545]

Several quite different processes appear to be responsible for the development of acquired enzymopathies.[546] Reversion to fetal hematopoiesis may alter enzyme function.[547] Posttranslational changes in normal enzyme protein have been demonstrated.[548] Synthesis of enzyme protein by developing erythroid cells may be impaired, perhaps as a result of alterations in chromosome number or disorderly and dyssynchronous nuclear maturation. Although some components of the abnormal pattern of enzymes (such as low PFK or high enolase activity) may suggest a reversion to fetal erythropoiesis, others do not. The possibility that these enzyme abnormalities may be familial and antedate the onset of an acquired blood disorder has not been fully explored.

CHAPTER 18

Glucose-6-Phosphate Dehydrogenase Deficiency

Lucio Luzzatto and **Vincenzo Poggi**

CHAPTER OUTLINE

G6PD IN RED BLOOD CELL METABOLISM
Structure and Biochemistry of G6PD
Genetics of G6PD
Features of G6PD in Red Blood Cells
Molecular Basis of G6PD Deficiency
Epidemiology of G6PD Deficiency
CLINICAL MANIFESTATIONS OF G6PD DEFICIENCY
Acute Hemolytic Anemia
Neonatal Jaundice
Congenital Nonspherocytic Hemolytic Anemia
LABORATORY DIAGNOSIS OF G6PD DEFICIENCY
Tests for G6PD Deficiency
GENOTYPE-PHENOTYPE CORRELATIONS
G6PD DEFICIENCY AND PREVENTIVE MEDICINE
G6PD DEFICIENCY IN NONERYTHROID CELLS
G6PD DEFICIENCY COEXISTING WITH OTHER DISORDERS
Association with Other Hematologic Diseases
Association with Nonhematologic Diseases
G6PD POLYMORPHISM AND MALARIA

Most hemolytic anemias can be categorized, at least at first approximation, as being either inherited or acquired as a result of either intracorpuscular or extracorpuscular causes. Hemolytic anemia associated with deficiency of glucose-6-phosphate dehydrogenase (G6PD) glaringly defies this categorization. Indeed, most persons with inherited G6PD deficiency have no anemia and almost no hemolysis; both develop only as a result of challenge by exogenous agents. Because the metabolic role of G6PD in red blood cells is primarily related to its reductive potential, the threat to G6PD-deficient red blood cells is oxidative damage. Therefore to understand hemolytic anemia associated with G6PD deficiency, we first need to define the physiologic role of G6PD[1-3] and pinpoint why the red blood cells are deficient in G6PD.[4,5,6]

G6PD IN RED BLOOD CELL METABOLISM

In metabolic maps, G6PD is commonly referred to as the first enzyme of the hexose monophosphate shunt, or the pentose phosphate pathway (Fig. 18-1). Although these time-honored phrases persist in textbooks, it is now clear that the main role of G6PD is not glucose utilization (G6PD accounts for less than 10% of that function); rather, its main role is production of the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH). NADPH has a crucial role in preventing oxidative damage to proteins and other molecules in all cells (Fig. 18-2).[7,8] This role is particularly crucial in red blood cells because, being oxygen carriers par excellence, they have a literally built-in danger of damage by oxygen radicals generated continuously in the course of methemoglobin formation.[9] The highly reactive oxygen radicals either decay spontaneously or are converted by superoxide dismutase to hydrogen peroxide (H_2O_2), which is still highly toxic. Detoxification of H_2O_2 to H_2O is effected by catalase[10] and glutathione peroxidase[11] (GSHPX). NADPH is crucial for the function of both these enzymes; it is a structural component of catalase[12] and is required as a substrate by glutathione reductase, which regenerates reduced glutathione (GSH) when it has been oxidized to oxidized glutathione by GSHPX (see Fig. 18-2). G6PD-deficient red blood cells are highly vulnerable to oxidative damage (discussed later in this chapter), even though G6PD deficiency is never complete in humans. When complete G6PD deficiency was produced in mouse embryonic stem cells by targeted inactivation of the G6PD gene,[13] the G6PD-null cells thus obtained were viable, but they formed colonies only in a low-oxygen environment; even so, they had an impaired capacity to form erythroid colonies.[14] When G6PD-null embryonic stem cells were injected into mouse blastocysts, chimeric embryos were obtained, and germline transmission was achieved; however, only female heterozygous mice were obtained because hemizygous male embryos died.[15] Thus a G6PD-null mutation is an embryonically lethal condition.

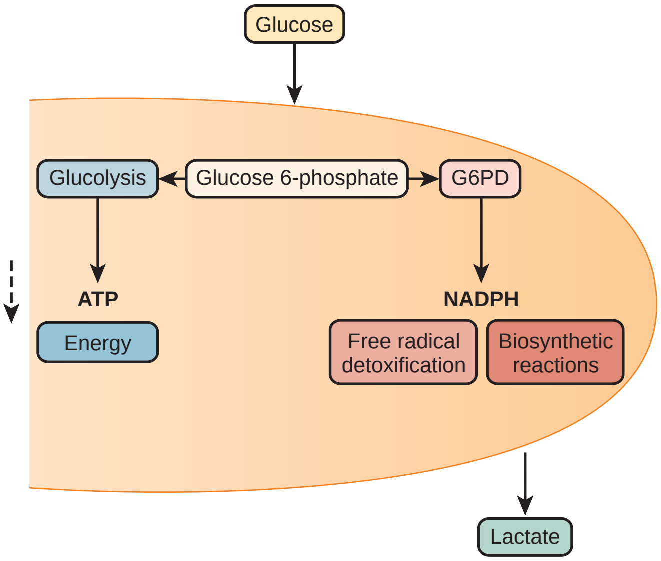

Figure 18-1 The role of glucose-6-phosphate dehydrogenase *(G6PD)* in red blood cell metabolism. As a somewhat crude oversimplification, after phosphorylation to G6P, glucose can be visualized as being at the bifurcation between two major pathways: glycolysis, which produces adenosine triphosphate *(ATP)*, and the pentose phosphate pathway, which generates reducing power (reduced nicotinamide adenine dinucleotide phosphate *[NADPH]*). Under "normal" conditions, probably less than 1% of G6P enters the pentose phosphate pathway, whereas under maximal oxidative stress, the amount may reach 10%.

Structure and Biochemistry of G6PD

G6PD is a ubiquitous enzyme that must be quite ancient in evolution because it has been found in all organisms, from prokaryotes to yeasts, protozoa, plants, and animals.[2,16,17] In mammals, G6PD is a good example of a housekeeping enzyme produced by a housekeeping gene; indeed, the gene is expressed in all cells of the body. G6PD is a typical cytoplasmic enzyme, although some G6PD activity is associated with peroxisomes in liver and kidney cells.[18] This finding is consistent with the view that these organelles have evolved as part of the need of early eukaryotes to defend against oxygen, which is germane to the role of G6PD today.

The enzymatically active form of G6PD is either a dimer or a tetramer (Fig. 18-3) of a single polypeptide subunit of about 59 kD.[19] The complete primary structure of the human enzyme has been deduced from the sequence of a full-length complementary deoxyribonucleic acid (DNA) clone.[20] The amino acid sequence of rat liver G6PD shows 94% homology to the human sequence and provides evidence that the N-terminal amino acid is *N*-acetylalanine, which must result from posttranslational cleavage of the N-terminal methionine. The same is probably true of the human enzyme.[21]

Extensive data are available on the kinetics of G6PD. Its coenzyme specificity is exquisite; human G6PD has practically no activity with nicotinamide adenine dinucleotide. Its substrate specificity is also very high because activity on other hexose phosphates (e.g., mannose 6-phosphate or galactose 6-phosphate) is negligible. The affinity for nicotinamide adenine dinucleotide phosphate (NADP) is about one order of magnitude higher than the affinity for glucose 6-phosphate (G6P).[2,16]

In the three-dimensional structure of G6PD (see Fig. 18-3),[22-26] one sees that the G6P binding site is near K205, and the critical role of this amino acid in electron transfer[27] has been confirmed by showing that replacing it with threonine nearly abolishes catalytic activity.[28] The NADP binding site is located near a fan of β-sheet structures, with a critical G-X-X-G-X-X peptide motif corresponding to amino acids 38 to 43 encoded in exon 3. Interestingly, the presence of a molecule of "structural" NADP, which had been suggested by early biochemical work,[29] has been confirmed.[24]

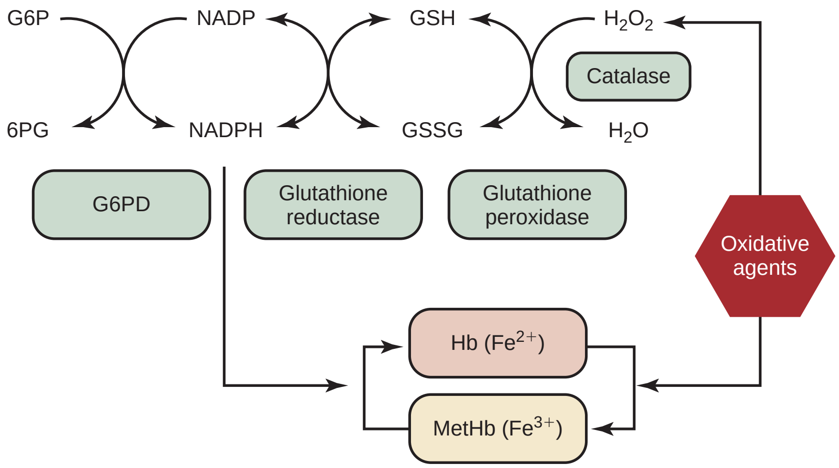

Figure 18-2 Glucose-6-phosphate dehydrogenase *(G6PD)* and the glutathione *(GSH)* cycle. The front-line defense against oxidative damage by hydrogen peroxide *(H_2O_2)* is GSH by means of GSH peroxidase. GSH peroxidase uses up GSH, and its regeneration can be effected in the red blood cell only through GSH reductase (GSSGR) by reduced nicotinamide adenine dinucleotide phosphate *(NADPH)*, which is ultimately provided by G6PD. *G6P,* Glucose-6-phosphate; *Hb (Fe^{2+}),* ferromethemoglobin; *MetHb (Fe^{3+}),* ferrimethemoglobin; *NADP,* nicotinamide adenine dinucleotide phosphate; *6PG,* 6-phosphogluconate. *(Modified from Luzzatto L, Mehta A, Vulliamy T: Glucose-6-phosphate dehydrogenase deficiency. In Scriver C, Beaudet A, Sly W, et al, editors:* The metabolic & molecular bases of inherited disease, *ed 8, New York, 2001, McGraw-Hill, p. 4517–4553.)*

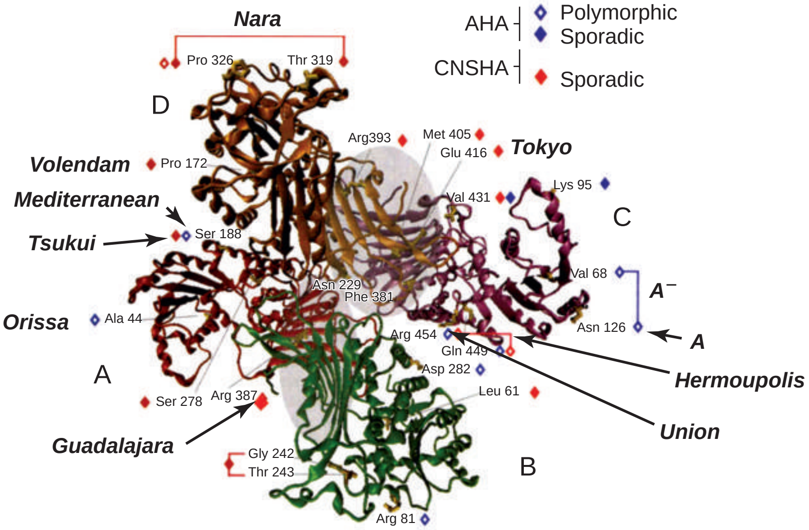

Figure 18-3 The three-dimensional structure of the human glucose-6-phosphate dehydrogenase (G6PD) tetramer. The structure of the dimer was modeled first,[22] and then the tetramer structure was solved[23,24] and the details of substrate binding were elucidated.[25,26] A to D are the four identical monomers. The tetramer is a dimer of a dimer, and both the dimer and the tetramer are enzymatically active, whereas the monomer is not enzymatically active. The monomer consists of two domains—a smaller coenzyme domain encompassing residues 1 to 198 and a larger β+α domain consisting of residues 199 to 514. The *gray background* outlines, within each dimer, the critical area of the monomer-monomer interface, in which 57 amino acid residues are involved. Only some of the many mutations known are indicated; most of those in the dimer interface cause severe G6PD deficiency with congenital nonspherocytic hemolytic anemia (CNSHA). *AHA,* Acute hemolytic anemia (see Table 18-1). *(Modified from Mason PJ, Bautista JM, Gilsanz F: G6PD deficiency: the genotype-phenotype association.* Blood Rev *21:267–283, 2007.)*

Although many natural and nonnatural substances can affect the activity of G6PD, it is not certain which ones may be important physiologically. NADPH, one product of the G6PD reaction, is a potent quasicompetitive inhibitor,[30] and because most of the coenzyme in cells is in the reduced form,[31] it can be assumed that G6PD is normally under strong inhibition. Because the normal intracellular concentrations of both G6P and NADP are lower than their respective Michaelis constant (K_m) values, it is likely that these two substrates themselves are the main regulators of intracellular G6PD activity, together with NADPH. Any oxidative event affecting the cell will alter the NADPH/NADP ratio in favor of NADP. The simultaneous increase in NADP and decrease in NADPH act additively to increase G6PD activity by increasing the substrate drive on the reaction rate and decreasing product inhibition.[8] Under most conditions this may be the most important short-term regulatory signal, although it is, of course, possible that other regulatory effects play a role as well. Recently, as part of a study of the role of microribonucleic acids in Duchenne muscular dystrophy myoblasts, it has been discovered that miR-1 is a powerful negative regulator of G6PD synthesis.[32] Although not relevant to mature red blood cells, this phenomenon may be important in determining the G6PD level in nucleated cells both physiologically and under stress conditions.

Notes on Terminology

G6PD is the accepted abbreviation for the enzyme glucose-6-phosphate dehydrogenase (E.C. 1.1.1.49); the G6PD gene is designated *G6PD* or *Gd*.[4,16] Because *Gd* is X-linked (discussed later in this chapter), males can be only normal hemizygotes (*Gd*+) or deficient hemizygotes (*Gd*–); females can be normal homozygotes (*Gd*+/*Gd*+), deficient homozygotes (*Gd*–/*Gd*–), or heterozygotes (*Gd*+/*Gd*–). The phenotype of the last group is often referred to as "intermediate" because their overall red blood cell G6PD level usually lies in between the normal and the deficient range; however, exceptions do occur and will be discussed later in this chapter. Consequently, G6PD deficiency should not be regarded as a recessive but rather as a codominant trait. In this chapter, by *G6PD deficient,* we mean Gd^{-} males and Gd^{-}/Gd^{-} females; Gd^{+}/Gd^{-} females will have some degree of G6PD deficiency, but for clarity, we will always specify heterozygotes. According to a classification introduced in 1966 (Table 18-1), G6PD-deficient variants that result in congenital nonspherocytic hemolytic anemia (CNSHA) are designated class I; G6PD-deficient variants that do not result in CNSHA are designated class II or class III, depending on the severity of the reduction in enzyme activity in red blood cells. The separation between class II and class III is blurred and probably no longer useful. Class IV variants are those with normal activity. Class V was reserved for variants with increased activity, but after an initial report (G6PD Hektoen[33]), none has been found. In practice, because the majority of G6PD-deficient persons are mostly asymptomatic, their G6PD deficiency is referred to as mild, simple, or common (corresponding to class II or III); the minority of persons who have CNSHA are referred to as having rare, sporadic, or severe G6PD deficiency (corresponding to class I).

When a diagnostic test for G6PD is carried out, the phrase "positive result" is sometimes used to indicate that the test has shown G6PD deficiency. Use of this phrase has caused confusion, and its use should be avoided;

TABLE 18-1 Heterogeneity and Clinical Expression of Glucose-6-Phosphate Dehydrogenase Deficiency

Class*	Clinical Manifestations†	G6PD Activity (% of Normal)	No. of Known Mutant Alleles‡	Examples	Comments
IV	None	>85	2	A,B	G6PD B is the normal "wild type"
II + III	Asymptomatic in the steady state, but risk for NNJ, AHA, favism	<30	75	Med, A^-, Orissa, Mahidol, Canton Vanua Lava, Seattle	Most of these variants are known to be polymorphic
I	NNJ (severe), CNSHA	<10 in most cases	61	Sunderland, Nara, Guadalajara	Never polymorphic, but the same mutation can recur

AHA, Acute hemolytic anemia; *CHSHA,* congenital nonspherocytic hemolytic anemia; *NNJ,* neonatal jaundice.

*The separation between class II and class III is blurred and, in our opinion, is no longer useful.

†In brief, variants in class II and III can be regarded as having a *mild* phenotype confined to *acute* episodes; variants in class I have a *severe* phenotype with *chronic* illness.

‡See Fig. 18-4, *B*. We have counted only variants for which the mutation is known and the clinical expression is clearly reported.

instead, one should indicate that the test has shown either a *normal* result or a *deficient* result.

Genetics of G6PD

Gd, the G6PD gene, is located near the telomeric region of the long arm of the X chromosome[34-36] (band Xq28); historically, *Gd* has been a valuable X-linked genetic marker and a precious tool for studying the X-chromosome inactivation phenomenon[37,38] and clonal populations of somatic cells.[39-41] The *Gd* region was also one of the first regions of the human genome to be fully sequenced.[42]

X-linkage of *Gd* has three major consequences: (1) *Gd* mutations display the typical pattern of mendelian X-linked inheritance[43]; (2) severe G6PD deficiency is much more common in males than in females; and (3) as a result of X-chromosome inactivation, females who are heterozygous for two different *Gd* alleles exhibit somatic cell mosaicism.[37,44] As a result, if one of the alleles entails enzyme deficiency, about half the cells will be G6PD(+) and the other half will be G6PD(–), although there is a large range of variation around that average[45,46] for various reasons, not all of them fully known. At first approximation it can be assumed that X-inactivation takes place at random, and therefore a binomial distribution would be expected; the width of this distribution depends on the number of cells in the embryo or in individual embryonic tissue at the time of X-inactivation. If this number is 32 to 64, a fraction of about 2% of women with an "extreme phenotype" is predicted, that is, with less than 5% of one of the two cell types; this prediction is in good agreement with observation in an unselected sample of *Gd*+/*Gd*– heterozygotes,[46] although some studies have suggested an even larger proportion.[47]

Thus in many cases unbalanced or skewed phenotypes may arise simply by chance, according to the laws of statistics. However, in certain cases evidence exists of selection at the somatic cell level after X-chromosome inactivation. This finding was first well established in women who are heterozygous for hypoxanthine phosphoribosyltransferase deficiency,[48] and it has also been observed in several women heterozygous for severely deficient G6PD variants.[49,50] In these cases one must infer that the G6PD(–) state is a selective disadvantage for hematopoietic stem cells; interestingly, this disadvantage is cell lineage–specific because it does not affect, for instance, fibroblasts.[49] Finally, because selection might take place at other X-linked loci,[51] heterozygotes exhibiting extreme phenotypes by analysis of G6PD may arise from selection acting on an allele at another locus (a "hitchhiking effect"), as has been suggested in a family with G6PD Ilesha.[52-54] Evidence indicates that skewing may increase with age.[55]

At the genomic level, the *Gd* gene (Fig. 18-4, *A*) consists of 13 exons, the first of which is noncoding.[56] The total length of the gene is about 18.5 kilobases (kb), much of which (about 12 kb) consists of intron 2. The significance of this large intron is unknown; it may be important for efficient transcription or for processing because it is still the largest intron, even in the compressed version of the *G6PD* gene found in the puffer fish *Fugu rubripes*.[57] The promoter region has a high proportion of guanine (G) and cytosine (C) residues (i.e., it is GC-rich), as found characteristically in other housekeeping genes.[58] Deletion analysis has revealed that the "essential" portion of the promoter is only about 150 base pairs long.[59] Within this region, two Sp1 binding sites have been identified, either of which is essential for promoter activity.[60] This region and other regions are highly conserved between human and mouse,[61] thus supporting the notion that they are important for gene regulation.

Features of G6PD in Red Blood Cells

Only one structural gene exists for G6PD, although a related autosomal hexose dehydrogenase also exists.[62,63] Biochemical evidence is in keeping with the notion that the G6PD protein in red blood cells is the same as that in other somatic cells; thus when red blood cells are severely deficient in G6PD, this deficiency is also found to a greater or lesser degree in other somatic cells.[16] However, a significant difference in the metabolism of G6PD arises from the characteristic inability of mature red blood cells to synthesize protein. As a result, whereas in most somatic cells G6PD is subject to turnover, in red blood cells any G6PD molecule undergoing denaturation or proteolytic breakdown cannot be replaced (this

Figure 18-4 The human glucose-6-phosphate dehydrogenase *(G6PD)* genomic gene (**A**) showing exon-intron organization and a map of many of the known mutations (**B**). All variants shown, except G6PD A, are associated with enzyme deficiency. Mutations below the diagram are associated with a severe phenotype (class I), all of which are sporadic and rare. Mutations above the diagram are associated with a mild phenotype (class II or III), many of which are polymorphic, and some of those that have been more extensively investigated are shown by *initialed lollipop symbols*. A– is heterogeneous because it can result from a combination of the N126D replacement with any of three additional mutations. However, in the large majority of instances (probably more than 90%), the second mutation of G6PD A– is V68M.

condition is true, of course, not only for G6PD but also for most other red blood cell enzymes[64]). In normal red blood cells, the decay of G6PD approximates an exponential (see Fig. 18-6) with a half-life of about 60 days,[65] although it has been claimed that it may more closely approximate a two-slope curve with very fast breakdown when reticulocytes mature to erythrocytes and much slower breakdown subsequently.[66] The age dependence of red blood cell G6PD activity is so characteristic that it can be almost regarded as a marker of red blood cell age. In normal blood, reticulocytes have about five times more activity than the 10% oldest red blood cells.[67]

Molecular Basis of G6PD Deficiency

In principle, genetically determined deficiency of G6PD, like that of any other protein, might be attributed either to quantitative changes, such as mutations that affect the amount of the enzyme but not its structure, or to qualitative changes, such as mutations that affect the structure of the enzyme and hence its stability or catalytic efficiency. Extensive investigations of G6PD from G6PD-deficient cells, mostly carried out before the sequence of G6PD was known, revealed that (1) enzyme activity, even when severely reduced (sometimes to less than 1% of normal), is never completely absent and (2) enzymic properties (K_m, K_i, activity on substrate analogues, and thermostability, for example) are often different from those of the normal enzyme[8] (i.e., G6PD deficiency is associated with qualitative abnormalities). These data are consistent with point mutations in the coding region. In fact, from a database[68] of 186 mutant alleles that are now known, a reasonably clear pattern has emerged (see Table 18-2).

1. In nearly all G6PD variants there is a *single amino acid replacement* caused by a single missense point mutation.
2. In several of the cases in which two amino acid replacements are found, one of them is that of G6PD A (N126D). Because this nondeficient G6PD variant is polymorphic in Africa, the most likely explanation for the presence of two mutations in *cis* is that a second point mutation has taken place in a *Gd*^{A} gene.
3. Ten internal gene deletions have been discovered, all of them in frame (see Table 18-2); we can presume that deletions causing frameshifts would be lethal.
4. Only two mutations affecting splicing[68] have been discovered thus far.
5. The majority of the mutations (see Fig. 18-4, *B*) in the database[68] are sporadic, and most of them have been detected because they result in G6PD deficiency and CNSHA by causing sufficient loss of activity in red blood cells to become limiting for their in vivo survival. Sporadic variants associated with CNSHA are not likely to spread. However, in several instances the same variant has been encountered recurrently (for instance, we have found G6PD Tokyo in Scotland,[69] G6PD Guadalajara has turned up in Japan[70] and Belfast,[69,71] and G6PD Nara has been observed at least three times).[72] That the same mutation may be found recurrently in people who are almost certainly not ancestrally related is not trivial; these observations corroborate the notion that specific subtle constraints must exist whereby a particular G6PD variant has a distinctly

TABLE 18-2 Classification of 186 Known Human Glucose-6-Phosphate Dehydrogenase Mutations

Type of Mutation	Type of Mutation	No. of Mutants	Comments
Missense point mutations	Single	159	At least 35 of these mutations are polymorphic
	Two	13	6 of these mutations share the N126D mutation found on its own in the polymorphic nondeficient G6PD A: all of these are polymorphic, and 3 of them are the so-called G6PD A– common in Africa and in people of African descent 1 has the G6PD Canton mutation plus another mutation 1 of these has two mutations, one of which alone is known to cause CNSHA, and the other may aggravate the clinical picture[243]
	Three	2	One of these has two mutations characteristic of G6PD A– plus a third mutation causing CNSHA[244]

CHSHA, Congenital nonspherocytic hemolytic anemia; *G6PD*, glucose-6-phosphate dehydrogenase.

severe clinical expression but remains compatible with life.

6. The majority of known polymorphic mutations (Fig. 18-5) again are associated with G6PD deficiency, and overwhelming evidence indicates that they have become polymorphic as a result of malaria selection (discussed later in this chapter). For these mutations we can visualize more stringent constraints; indeed, although still causing deficiency in red blood cells, they must not affect them so severely that the advantage with respect to malaria is outweighed.
7. The pattern of G6PD mutations, whereby null mutations (such as nonsense mutations, frameshifts, or large deletions) are conspicuously absent, is in striking contrast to that seen in other inherited disorders, such as the thalassemias, hemophilia, and muscular dystrophy. An important functional difference between these conditions and G6PD deficiency is that the former result from mutations in tissue-specific genes, whereas *Gd* is a housekeeping gene. When a tissue-specific gene is totally inactivated by a mutation, it may cause severe disease but will not necessarily have interfered with embryonic development. By contrast, we know that G6PD-null mutations are lethal to the mouse embryo[15]; they probably occur in humans, but we never see them because they must be lethal in the human embryo as well. Some clue regarding what mutation can cause G6PD deficiency has come from alignment of the amino acid sequence of G6PD from 42 different organisms. A striking correlation was found between the amino acid replacements that cause G6PD deficiency in humans and the sequence conservation of G6PD.[17] Interestingly, two thirds of such replacements are in highly and moderately conserved (50% to 99%) amino acids, and relatively few are in fully conserved amino acids (where they might be lethal) or in poorly conserved amino acids, where presumably they simply would not cause G6PD deficiency.
8. The biochemical mechanism of G6PD deficiency is strongly contingent on the fact that in normal red blood cells, G6PD decreases exponentially as red blood cells age, with a half-life of about 50 days (as discussed earlier in this chapter). Because G6PD is an oligomeric globular protein, it is not surprising that many point mutations producing replacement of individual amino acids can further decrease the stability of G6PD; in fact, for most mutants, enzyme instability is the main mechanism of enzyme deficiency (Fig. 18-6).[6,68,73] In a few cases (e.g., G6PD Orissa[74] and G6PD Mahidol[75]), altered catalytic function (instead of or in addition to protein instability) may be the main mechanism of G6PD deficiency. The instability is most extreme when the binding of structural NADP is compromised[76] or when the amino acid involved is at the interface between the two subunits of G6PD; in such cases the dimer does not form or falls apart.[24] These situation apply to G6PD mutants that cause the most severe clinical phenotypes (that of CNSHA, as will be discussed later).

Recent studies on the rare disease incontinentia pigmenti have revealed the remarkable fact that the underlying gene, called *IKBKG/NEMO*, overlaps with *Gd,* is transcribed in the opposite direction, and shares one of its two promoters with *Gd*. Some patients with incontinentia pigmenti have large deletions that remove four exons of *G6PD*[77]; however, no G6PD deficiency has been reported in this unique situation because all affected patients are heterozygotes and presumably in the blood there is overwhelming selection in favor of the cells in which the active X chromosome has the normal Gd allele.

Epidemiology of G6PD Deficiency

The geographic distribution[78] of G6PD deficiency is rather extraordinary in two ways. First, it has a very high prevalence overall, with more than 500 million people estimated to be involved (most of them mostly asymptomatic). Second, it has a high prevalence in many populations in most tropical and subtropical parts of the world

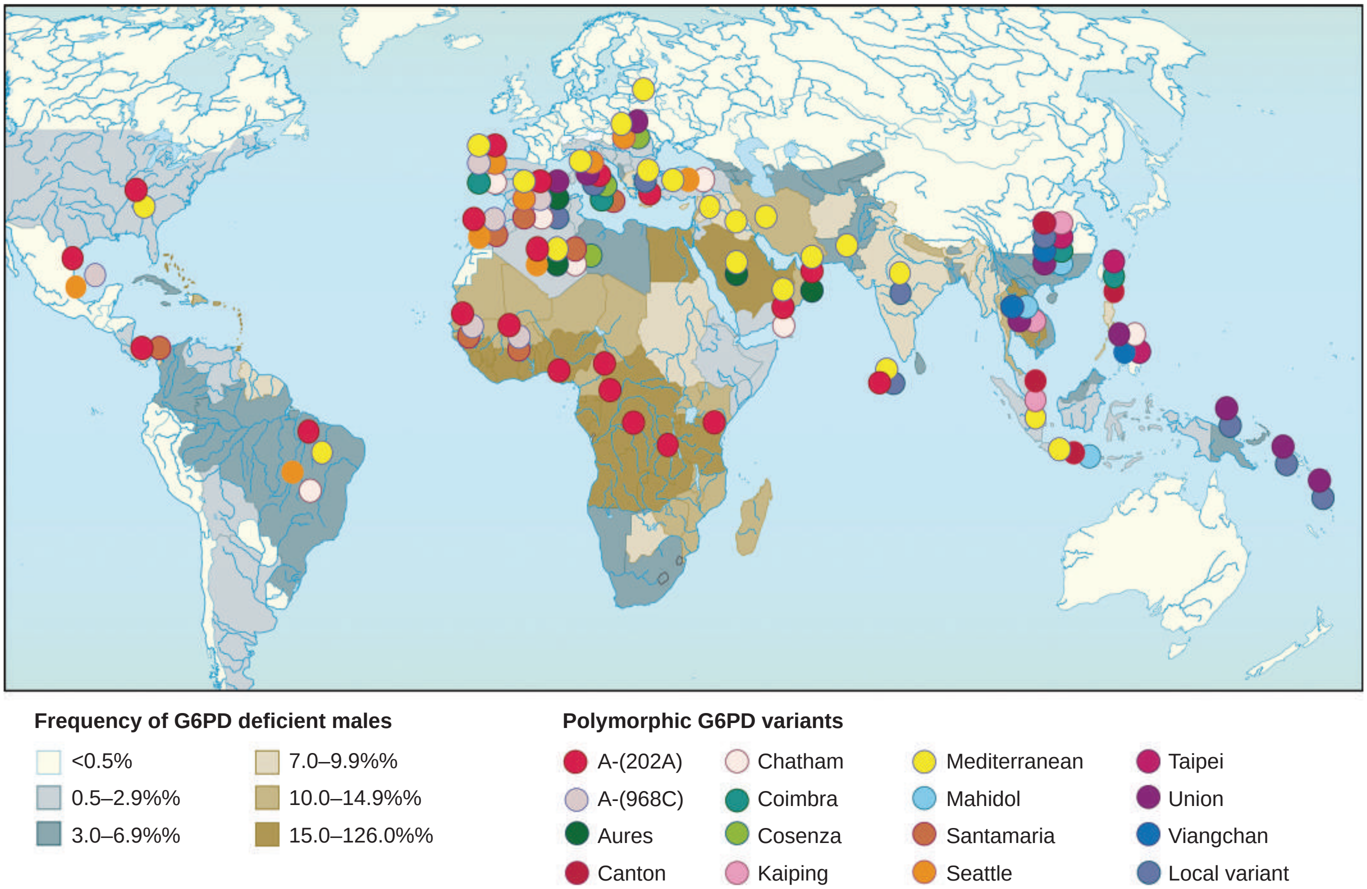

Figure 18-5 A world map of glucose-6-phosphate dehydrogenase *(G6PD)* deficiency. The shadings indicate the overall prevalence of G6PD deficiency in individual countries; the distribution of individual G6PD variants is shown by colored symbols. *(Modified from WHO Working Group: Glucose-6-phosphate dehydrogenase deficiency.* Bull World Health Organ *67:601–611, 1989; and Tan KL, Boey KW: Clinical experience with phototherapy.* Ann Acad Med Singapore *18:43–48, 1989.)*

because of malaria selection (see Fig. 18-5 and the last section in this chapter). Thus G6PD is prevalent in all five continents; however, it has never been reported in Amerindians, perhaps because they have been exposed to malaria only during the past three centuries. Very recently a new map of G6PD deficiency in malaria-endemic areas has been produced.[79]

CLINICAL MANIFESTATIONS OF G6PD DEFICIENCY

The most classic manifestation of G6PD deficiency is acute hemolytic anemia (AHA); in infants, however, another syndrome of great clinical and public health importance is neonatal jaundice (NNJ). CNSHA is a much rarer manifestation of G6PD deficiency and is the result of a lifelong hemolytic process. These different clinical manifestations are discussed in turn.

Acute Hemolytic Anemia

Clinical Picture

A child with G6PD deficiency is clinically and hematologically normal most of the time, and this status can be designated as a steady-state condition. However, a rather dramatic clinical picture can develop upon ingestion of fava beans (favism),[80] during the course of infection, or after exposure to certain oxidative agents (see Table 18-3).

Favism. After a lag of hours since eating fava beans, the child may become fractious and irritable or subdued and even lethargic. Within 24 to 48 hours the child's temperature is often moderately elevated. Nausea, abdominal pain, diarrhea, and rarely vomiting may be present. In striking contrast to these relatively nonspecific symptoms, the patient or a parent will observe, within 6 to 24 hours, the telltale and rather frightening sign of discolored urine (Fig. 18-7). The urine will be reported as dark; as red, brown, or black; or as "passing blood instead of water." Depending on experience, culture, and socioeconomic background, it will be said to resemble Coca-Cola, strong tea, or port wine. At about the same time, jaundice will become obvious. Physical examination may reveal little more than the signs corresponding to these symptoms. The child will be pale and tachycardic, and in severe cases evidence may be seen of hypovolemic shock or, less likely, heart failure. The spleen is usually moderately enlarged, and the liver may also be enlarged; either or both may be tender.

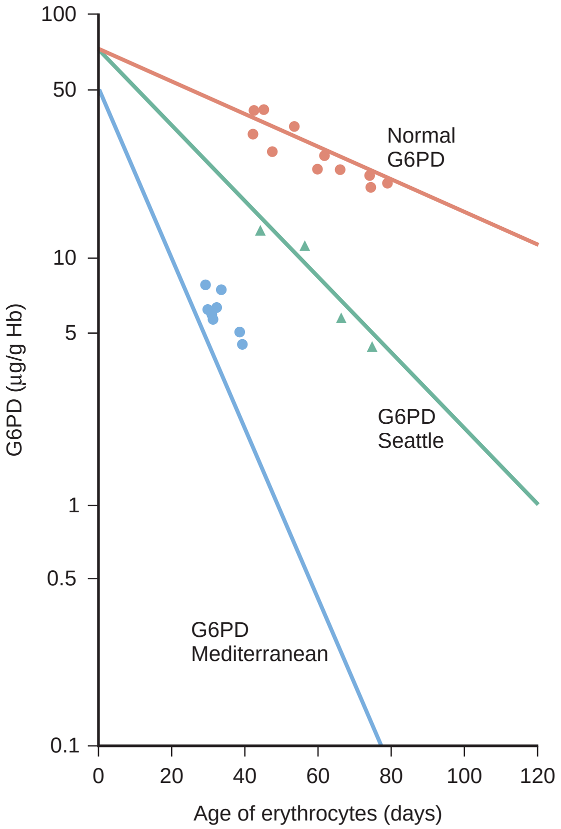

Figure 18-6 The main mechanism of glucose-6-phosphate dehydrogenase *(G6PD)* deficiency in red blood cells is in vivo instability of mutant enzyme. For many G6PD variants, such as the two studied here, this is essentially acceleration of a process that takes place normally with the aging of red blood cells in the circulation. *Hb,* Hemoglobin. *(Modified from Morelli A, Benatti U, Gaetani GF, et al.: Biochemical mechanisms of glucose-6-phosphate dehydrogenase deficiency.* Proc Natl Acad Sci U S A *75:1979–1983, 1978.)*

Drugs. G6PD deficiency was first discovered by investigating a possible genetic basis for sensitivity to primaquine, and early studies have documented the clinical manifestation of primaquine-induced AHA in G6PD-deficient volunteers who were adults.[81] In children with G6PD deficiency the largest reported series of AHA is not with primaquine but with dapsone.[82] The children were from different parts of Africa, but because they all received the same dose, quantitative data could be obtained for the first time. In 119 G6PD-deficient (hemizygous or homozygous) children with malaria who received 7.5 mg/kg of dapsone over 3 days, the drop in hemoglobin averaged about 2 g/dL, with a nadir on day 7. An increase in neutrophils and a brisk reticulocyte response were noted, and the bilirubin peaked on day 3.

Laboratory Findings

Anemia may range from moderate to extremely severe (hemoglobin values of 2.5 g/dL have been recorded). In the absence of other preexisting hematologic abnormalities, the anemia is normocytic and normochromic. The structure of the red blood cells may be striking (Fig. 18-8, *A*). Marked anisocytosis is often noted (reflected as a wide red blood cell size distribution on the electronic counter) because of the coexistence of large polychromatic cells and "contracted" cells, some of which can be frankly classified as spherocytes. Marked poikilocytosis is also noted with the presence of distorted red blood cells, "irregularly contracted" red blood cells, and red blood cells with apparently uneven distribution of the hemoglobin inside them (hemighosts).[83] Although some of these appearances are probably smearing artifacts, electron micrographic evidence suggests that in some of the cells, opposing surfaces of the membrane have become "cross-linked."[84] Probably the most characteristic poikilocytes are those in which the cell margin literally appears dented, as though a portion has been plucked out or bitten away ("bite cells"; see Fig. 18-8, *A*). The reticulocyte count is increased and may reach peaks of 30% or greater, with an elevated percentage of the immature reticulocyte fraction, reflecting a prompt and effective bone marrow response. Careful inspection of reticulocyte preparations may reveal inclusion bodies different from those normally seen in reticulocytes; these bodies are

TABLE 18-3 Drugs That Can Trigger Hemolysis in Glucose-6-Phosphate Dehydrogenase–Deficient Subjects*

Other	Rasburicase Toluidine blue	Ascorbic acid Glibenclamide Vitamin K

*The literature on this subject was critically reviewed by Youngster et al.[245] in 2010, and we took this review into account when revising the table that appeared in previous editions. However, we believe that the notion of levels of evidence used to assess the efficacy of drugs cannot be applied in the same way to assess the safety of drugs. Therefore we believe that even individual case reports, if convincingly documented, must be taken seriously, and thus this table has some differences with respect to the article by Youngster et al.

†There has been a revival in the use of methylene blue (MB), together with artemisinin-based combinations, in the treatment of *Plasmodium falciparum* malaria, because MB also has a gametocytocidal action. At the doses used, MB has caused significant hemolysis in children in Africa[246]; most cases were not very severe.

‡Atovaquone has been found to be a safe alternative in a glucose-6-phosphate dehydrogenase–deficient patient with *Pneumocystis jiroveci* infection[247]; this might apply to other protozoal infections.

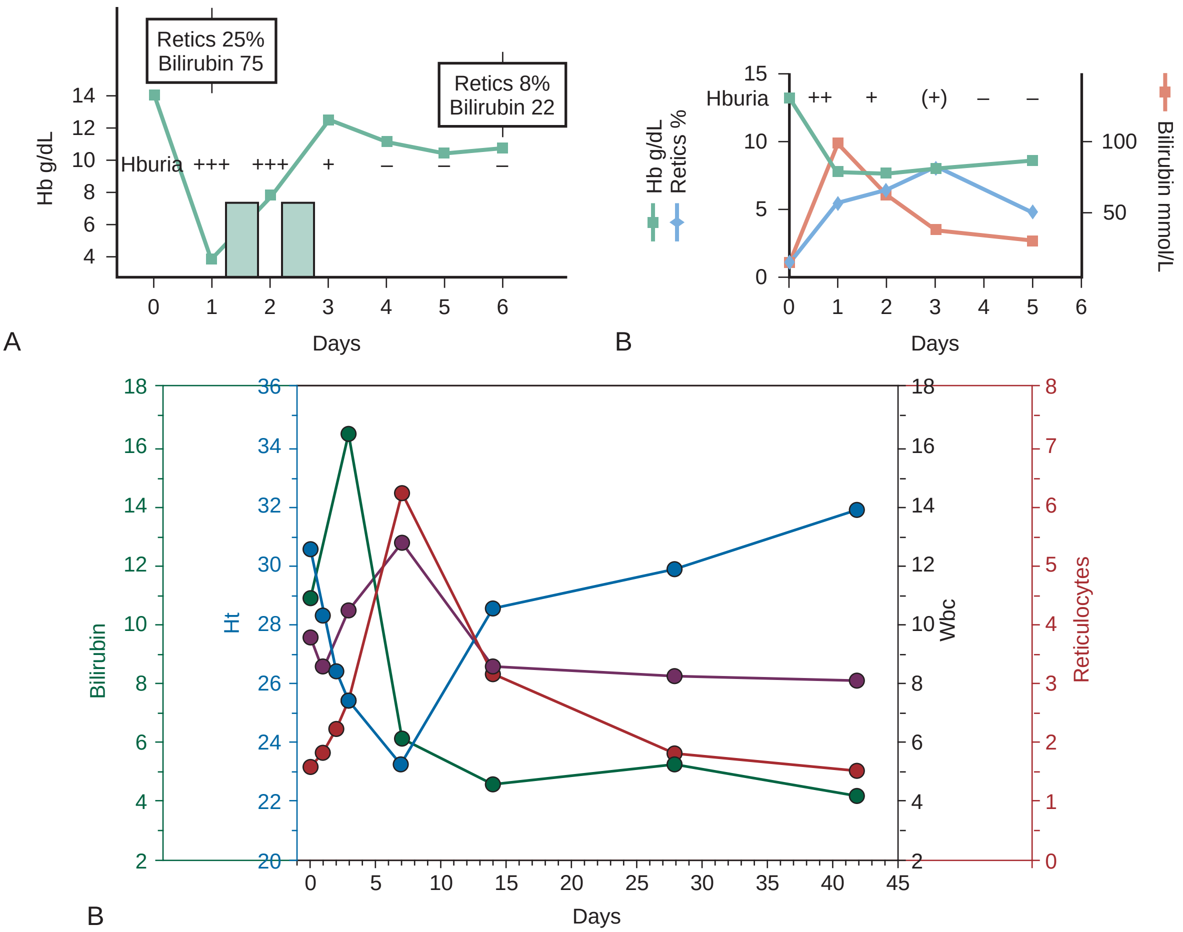

Figure 18-7 Clinical course of acute hemolytic anemia in glucose-6-phosphate dehydrogenase (G6PD) deficient children. **A,** A severe attack of favism in a 21-month-old boy, who required two blood transfusions *(bars)* because of life-threatening anemia after the ingestion of fava beans. The second blood transfusion was administered because of persistent hemoglobinuria (Hburia). The boy had severe G6PD deficiency (red blood cell G6PD activity less than 3% of normal; the underlying mutation was G6PD Mediterranean). The Hb value on day 0 is presumed. **B,** Hemolytic anemia caused by the administration of an antimalarial drug containing dapsone (2.5 mg/kg/day for 3 days) to children with acute (uncomplicated) *Plasmodium falciparum* malaria. Each curve represents the arithmetic mean of data from 95 male children with G6PD deficiency. The extent of the drop in hematocrit value indicates that, on average, about one fourth of red blood cells have undergone hemolysis; this is associated with a sharp increase in serum bilirubin. There is a brisk bone marrow response, with a peak on day 7 of both reticulocytes and leukocytes (mainly neutrophils). Although it is seen that with this dose of dapsone and with this G6PD variant the hemolytic anemia is on average less severe than that depicted in part **A,** 12 of the 95 children required a blood transfusion. Note that by the end of 6 weeks the blood counts are back to normal, with a hematocrit (Ht) value slightly higher than before treatment, presumably as a result of successful treatment of malaria. *Hb,* Hemoglobin; *Retics,* reticulocytes; *Wbc,* white blood cell. *(***A,** *Courtesy of Professor Tullio Meloni, Sassari, Sardinia.* **B,** *Modified from Pamba A, Richardson ND, Carter N, et al: Clinical spectrum and severity of hemolytic anemia in glucose 6-phosphate dehydrogenase-deficient children receiving dapsone.* Blood *120:4123–4133, 2012.)*

discrete, round, and 1 to 3 μm in diameter, and they usually appear to be leaning, from the interior, against the cell membrane. These inclusions are more clearly displayed by supravital staining with methyl violet and are referred to as *Heinz bodies* (see Fig. 18-8, *B*). They consist of precipitates of denatured hemoglobin and are the vivid manifestation of the oxidative insult that this protein and the cell itself has experienced. However, Heinz bodies are a very transient finding because they tend to be promptly "pinched off" by the spleen[85] (thus giving rise to bite cells), and the red blood cells that contain them are very rapidly removed from the circulation. Haptoglobin is reduced to the point of being undetectable. In severe cases it is possible to demonstrate free hemoglobin in plasma (*hemoglobinemia*). The white blood cell count is usually moderately elevated, with a predominance of granulocytes. The platelet count may be normal, increased, or moderately decreased. The unconjugated bilirubin level is elevated, but "liver enzyme" levels are generally normal. Test results of the dark urine are strongly positive for blood because of the presence of free hemoglobin (see the differential diagnosis of this sign in Table 18-4).

Clinical Course

In the majority of cases the hemolytic attack, even if severe, is self-limited and tends to resolve spontaneously (see Fig. 18-7, *B*). Depending on the proportion of red blood cells that have been destroyed, the anemia will be more or less severe, but the hemoglobin level may be back to normal in 3 to 6 weeks. However, in some cases the decrease in hemoglobin is so precipitous that blood

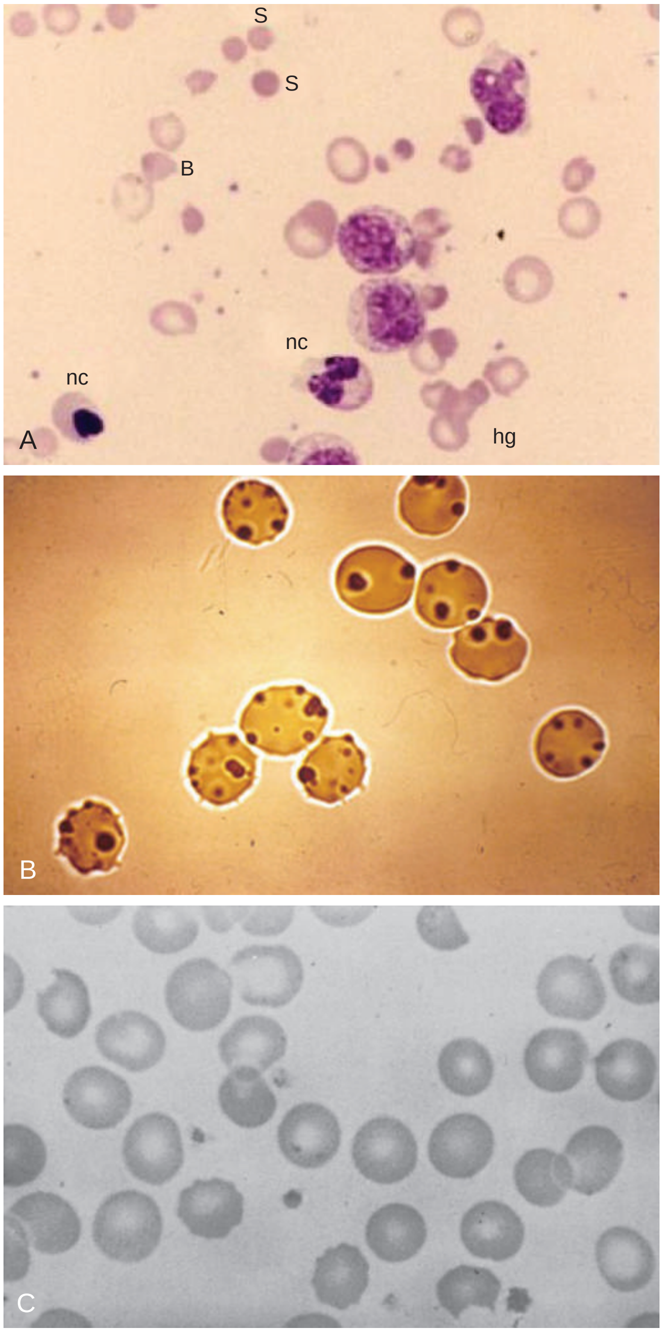

Figure 18-8 Blood smears in glucose-6-phosphate dehydrogenase (G6PD) deficiency. **A,** Acute hemolytic anemia (favism) characterized by marked morphologic abnormalities of red blood cells with anisocytosis, polychromasia, bizarre poikilocytes, "bite cells," and "hemighosts." Note the nucleated red blood cell and polymorphonuclear leukocytosis with a marked shift to the left. **B,** A supravital stain with methyl violet carried out at an early stage during an attack of favism demonstrates one or more Heinz bodies in individual red blood cells. **C,** Chronic nonspherocytic hemolytic anemia. The morphologic abnormalities are much less pronounced, but several poikilocytes and occasional bite cells are seen. *B,* Bite cells; *hg,* hemighosts; *nc,* nucleated cells; *S,* spherocytes.

transfusion is required to save the child's life. The proportion of such cases will depend primarily on (1) the dose of the offending agent, (2) concomitant pathology, and (3) the previous hemoglobin level. Although the blood urea level may be transiently elevated, the development of renal failure in children is exceedingly rare, even in the presence of massive hemoglobinuria (see Fig. 18-7, *A*).

Diagnosis

With a history of fava bean ingestion or of administration of a potentially hemolytic drug (see Table 18-3) followed by hemoglobinuria (see Table 18-4), the diagnosis is almost always straightforward, and it can be made quite confidently even before obtaining the final proof that the patient is deficient in G6PD (discussed later in this chapter). If the hemoglobinuria has already subsided and the history is uncertain, one is faced instead with the much wider differential diagnosis of AHA. Negative findings of a direct antiglobulin test will militate against autoimmune hemolytic anemia. In endemic areas it will be important to exclude malaria or the much rarer babesiosis. In persons with hemolytic-uremic syndrome, the red blood cell structure is different, and evidence of impaired renal function will be seen. In all cases, demonstration of G6PD deficiency will be conclusive, and in uncertain cases it will be crucial.

Pathophysiology

The clinical picture of AHA in a G6PD-deficient child is a vivid expression of the fact that, as we know already, hemolysis results from the action of an exogenous factor on latently but intrinsically abnormal red blood cells. Hemoglobinemia and hemoglobinuria unambiguously indicate that the hemolysis is at least in part intravascular. At first approximation we can visualize the following sequence of events: (1) an oxidative agent causes conversion of GSH to oxidized glutathione; (2) because of the limited capacity of G6PD-deficient red blood cells to regenerate GSH, their GSH reserve is rapidly depleted; (3) once GSH is exhausted, the sulfhydryl groups of hemoglobin and probably other proteins are oxidized to disulfides or sulfoxides; and (4) coarse precipitates of denatured hemoglobin cause irreversible damage to the membrane, and the red blood cells lyse or become prey to macrophages.

TABLE 18-4 Hemoglobinuria in Children

Condition	Circumstances	Diagnostic Approach
G6PD deficiency	Exposure to a trigger of hemolysis	Test for G6PD activity
Blackwater fever	Relatively rare complication of malaria	Blood slide for malaria parasites
Paroxysmal cold hemoglobinuria	Usually associated with viral infection	Test for Donath-Landsteiner antibody
Mismatched blood transfusion	Usually ABO incompatibility	Repeat crossmatch
Paroxysmal nocturnal hemoglobinuria	Tends to recur	Flow cytometry for CD59
Clostridium welchii septicemia	Burns, severe open trauma, transfusion of contaminated blood	Culture of blood or appropriate patient material

G6PD, Glucose-6-phosphate dehydrogenase.

Not all of these steps from oxidative attack to final hemolysis have been fully documented in vivo, in part because of one major difficulty: in the course of AHA the red blood cells sampled from the patient are obviously, at any given stage, those that have not yet hemolyzed. However, GSH depletion is a most characteristic finding when red blood cells are subjected to oxidative challenge,[86,87] and in one careful study it has been demonstrated that during an attack of favism, the first measurable biochemical change is a decrease in NADPH, followed by a decrease in GSH,[88] in keeping with stages 1 and 2 described earlier. Heinz bodies (see Fig. 18-8, *B*) are the visible expression of stage 3. Stage 4 is less clearly defined, although studies suggest that the abnormal proteolytic activity is associated with increased levels of intracellular calcium,[89,90] as well as binding of hemichromes (arising from denaturation of hemoglobin) to band 3 molecules.[91]

Even though intravascular hemolysis in persons with AHA that is associated with G6PD deficiency is important in pathophysiology and diagnosis, a substantial proportion of the hemolysis is extravascular (as shown by the enlarged spleen). Probably the most severely damaged red blood cells hemolyze in the bloodstream on their own, whereas less severely damaged red blood cells will be recognized as abnormal by macrophages and will undergo extravascular hemolysis in the reticuloendothelial system. This process has been referred to as an example of an "innocent bystander" phenomenon[92] (although the red blood cells, by virtue of being deficient in G6PD, are not that innocent), in which complement and immunoglobulins may be involved.[93] Finally, it is important to remember that the red blood cell destruction in AHA associated with G6PD deficiency is an orderly function of red blood cell age (see Fig. 18-6). The oldest red blood cells with the least G6PD are the first to hemolyze, and the hemolytic process progresses upstream toward cells with more and more G6PD.[94] As a result there is a selective enrichment in red blood cells that, despite being genetically G6PD deficient, have relatively higher levels of G6PD. This phenomenon can be so marked with certain G6PD variants that patients in the posthemolytic state are found to be relatively resistant to further challenge; thus the patient may be in a state of compensated hemolysis.[81]

Triggers and Mechanism of Hemolysis

After primaquine, numerous other drugs have been reported as being potentially dangerous in G6PD-deficient persons (Table 18-3). There is no obvious similarity in chemical structure among all of these substances, but they have in common the ability to stimulate the pentose phosphate pathway in red blood cells,[95] which must mean that they are able to oxidize NADPH directly or indirectly. The components of fava beans responsible for hemolysis have been identified as vicine and convicine, two β-glycosides that generate the aglycones divicine and isouramil.[96] These compounds, in the course of their auto-oxidation, produce free radicals, which in turn oxidize GSH and thereby activate the chain reaction of events previously outlined.[97] The drugs listed in Table 18-3, or their metabolites, act in a similar way. Henna dyes, which are used as cosmetics in several populations, mainly in Asia, can also cause serious hemolysis after absorption through the skin[98-101] or ingestion (apparently to induce an abortion[102]).

An intriguing feature of AHA associated with G6PD deficiency is its erratic character, which is more conspicuous with certain agents than with others. For instance, it is estimated that in adults, ingestion of fava beans does not trigger AHA in more than 25% of cases, and even in the same person, favism may occur on one occasion but not on another.[93] One obvious factor must be the amount of fava beans ingested (in relation to body mass). Another is the quality, with raw fava beans more likely to cause favism than cooked, frozen, or canned fava beans. Perhaps even more important is the finding that the glycoside content is a function of the maturity of the beans, with young, small beans being much richer (as well as more tasty!). With respect to drugs, primaquine causes hemolysis regularly, but aspirin does so only sometimes[103]; once again, the dosage must be important, but additional genetic or acquired factors affecting the metabolism of the drug may play a role. With regard to infection, the best documented precipitants are hepatitis, pneumonia, typhoid fever, and recently brucellosis[104] and *Clostridium difficile* (in newborns[105]); however, viral infections of the upper respiratory or gastrointestinal tract may also cause hemolysis.[106] Apparently trauma also can be a trigger. It has been reported that in a group of patients who had been involved in major road traffic accidents, the frequency and severity of infection were significantly higher in patients who were G6PD deficient, and more severe anemia also occurred in this group.[107]

Release of peroxides during phagocytosis of bacteria by granulocytes might explain the hemolytic process in persons with bacterial infections.[108] In this respect it is possible that hemolysis has sometimes been attributed to drugs used for treating infection when it should have been blamed on the infection itself.

Treatment

AHA in a child may be a diagnostic problem that, once solved, does not require any specific treatment at all; in other cases, the child's condition may be considered a medical emergency requiring immediate action. The most urgent question is whether a blood transfusion is needed. It is difficult to give absolute directives, but the following guidelines may be useful[109]:

1. If the hemoglobin level is less than 7 g/dL, the child should undergo a transfusion immediately.
2. If the hemoglobin level is less than 9 g/dL and evidence indicates persistent brisk hemolysis (hemoglobinuria), immediate blood transfusion is also indicated.
3. If the hemoglobin level is greater than 9 g/dL but hemoglobinuria persists or if the hemoglobin level is between 7 and 9 g/dL but the child has no hemoglobinuria, the child should be kept under close observation for at least 48 hours and should undergo a transfusion if either condition 1 or 2 develops.

The most important complication that may require treatment is acute renal failure, which is exceedingly rare in children.

Neonatal Jaundice

From an epidemiologic point of view, it is noteworthy that the frequency of NNJ varies widely in different populations; in many populations in which G6PD deficiency is prevalent, the rate of pregnancies at risk for Rhesus incompatibility happens to be low.[110,111] In addition, because Rhesus-related hemolytic disease of the newborn (HDN) is disappearing thanks to the implementation of appropriate prophylaxis, one can expect G6PD-related NNJ to be generally on the increase, at least in relative terms. G6PD deficiency has been well recognized as a major cause of NNJ in countries as disparate as Greece,[110] Nigeria,[112] and Taiwan.[113] During the past decade in the United States it has been increasingly recognized that G6PD deficiency is an important etiologic factor of severe NNJ, including kernicterus.[114,115]

Clinical Features

NNJ related to G6PD deficiency is very rarely present at birth; it has a peak incidence between day 2 and day 3.[116] Jaundice is present more often than anemia, and the anemia is very rarely severe.[117] For this reason the terms *HDN* and *NNJ* cannot be regarded as interchangeable, at least in the context of G6PD deficiency. The severity of G6PD-related NNJ varies from being subclinical to imposing the threat of kernicterus if not treated, and thus prompt recognition of the problem is extremely important to avoid crippling neurologic sequelae.[118-121]

Nature of the Association between G6PD Deficiency and Neonatal Jaundice

It is not fully explained why NNJ develops in some but not all G6PD-deficient newborns. Several clinical studies have established beyond any possible doubt that the association is statistically much higher than could be expected by chance (Table 18-5).[122] However, because not *all* G6PD-deficient newborns have NNJ (Table 18-6), it is likely that genetic or environmental factors (or both) are involved in addition to G6PD deficiency and that the same factors that are more extreme can also make the NNJ more severe. NNJ is not the prerogative of some G6PD variant because it is prevalent in widely remote parts of the world (e.g., Nigeria,[122] Sardinia,[123] Singapore,[124] and China[125]) in which the *Gd* alleles underlying G6PD deficiency are different; moreover, within both Sardinia[126] and Taiwan,[127] NNJ has been found in babies with any of several different G6PD variants. The possibility that NNJ correlates with the quantitative level of residual G6PD activity is controversial.[128,129] Specific features of erythrocytes in newborns such as elevated levels of ascorbic acid, depressed activity of glutathione reductase,[122] and low levels of vitamin E, GSHPX, and other enzymes[130] could contribute to the degree of jaundice. A dissociation has been reported between hyperbilirubinemia and anemia in G6PD-deficient neonates.[117,123] Indeed, in one series there was no difference in the distribution of hematocrit values in cord blood and on day 3 between G6PD-deficient newborns with and without jaundice, thus suggesting that to a large extent this jaundice may be of hepatic origin rather than hemolytic. In keeping with this notion, measurements of the bilirubin production-conjugation index have demonstrated that the NNJ in otherwise healthy G6PD-deficient neonates depends more on inefficient bilirubin conjugation than on hemolysis.[131] The *UGT1A* mutation characteristic of Gilbert syndrome is associated with a much higher risk for NNJ and kernicterus in G6PD-deficient babies.[132,133] In addition, environmental factors can certainly exacerbate NNJ, in some cases by causing hemolysis in individual G6PD-deficient newborns; such factors include prematurity, breastfeeding,[134] inhalation of naphthalene (camphor balls), acidosis, hypoxia, an infection such as viral hepatitis,[135] use of oxidant drugs, and ingestion of

TABLE 18-5 Association Between Glucose-6-Phosphate Dehydrogenase Deficiency and Jaundice in Newborns

drugs[136] or fava beans (favism in utero[137]) by the mother before delivery.

In summary, it is likely that two different types of NNJ are associated with G6PD deficiency: (1) a more common type (see Table 18-6) that can best be visualized as a marked exaggeration of "physiologic jaundice" (this type is usually clinically benign and not greatly influenced by the environment) and (2) a rarer, frankly hemolytic type that is more severe and can be visualized as AHA occurring in a newborn baby because the baby happened to be exposed to one of the same agents that could cause AHA even in an adult.

Severe NNJ can occur in girls heterozygous for G6PD deficiency.[138] In addition, in geographic areas where G6PD deficiency is very common, female newborns might be homozygous for the trait, thus behaving like a hemizygous G6PD-deficient male newborn.

Treatment

Management of NNJ associated with G6PD deficiency does not differ from that recommended for other causes. Thus mild cases do not require treatment; intermediate cases require phototherapy; and severe cases require exchange transfusion, just as in NNJ caused by "classic" HDN. Kernicterus is still an impending threat, especially when severe NNJ is associated with anemia, hypoxia, or infection. Clinical practice guidelines for the management of hyperbilirubinemia in newborns quote: "measurement of the glucose-6-phosphate dehydrogenase (G6PD) is recommended for a jaundiced infant who is receiving phototherapy and whose family history or ethnic or geographic origin suggest the likelihood of G6PD deficiency or for an infant in whom the response to the phototherapy is poor."[139] G6PD-deficient newborns must be considered as being "at high risk"[134] and therefore requiring greater surveillance and more intensive treatment of hyperbilirubinemia. Specifically, it is recommended that in term newborns, exchange transfusion be carried out if the serum bilirubin level exceeds 15 mg/dL in the first 2 days of life or 19 mg/dL at any time in the first week of life.

Congenital Nonspherocytic Hemolytic Anemia

A small minority of children with G6PD deficiency have hemolytic anemia not only when it is triggered by an exogenous factor but even in the steady state (Fig. 18-9). These children have special G6PD mutations (class I); all of them are rare, but they are scattered worldwide, regardless of whether G6PD deficiency is endemic in the region.

The patient is almost invariably male (with exceptions, discussed later) and in general is evaluated because of unexplained jaundice, frequently presenting at birth (NNJ). Unfortunately, anemia recurs and the jaundice fails to clear completely, thus requiring further investigation. In other cases, NNJ may have been overlooked or forgotten and the patient is reinvestigated only much later in life (e.g., because of gallstones in a boy or in a young adult). The severity of the anemia ranges from being borderline to being transfusion-dependent in different patients (Table 18-7). The anemia is usually normochromic but somewhat macrocytic because a large proportion of reticulocytes (up to 20% or more) will cause an increased mean corpuscular volume and a shifted, wider

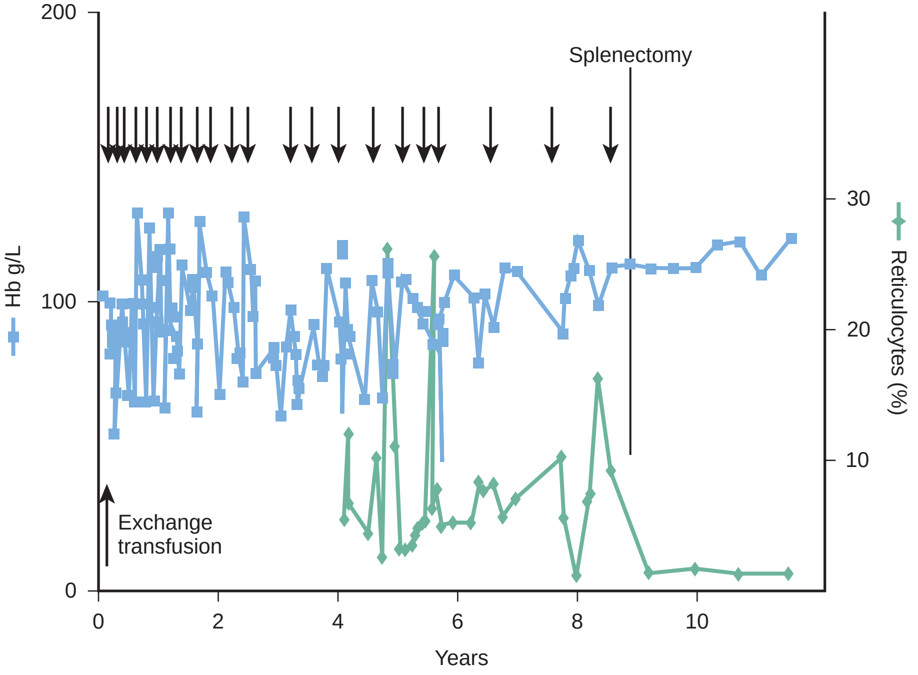

Figure 18-9 The clinical course of a boy with congenital nonspherocytic hemolytic anemia (CNSHA) caused by severe glucose-6-phosphate dehydrogenase (G6PD) deficiency. Severe neonatal jaundice was the initial manifestation; subsequently, the child developed normally but required numerous blood transfusions. The transfusion dependence remitted after splenectomy. Currently, the patient, now in his early twenties, has had a cholecystectomy; he has moderate anemia and is still jaundiced. The patient's *Gd* mutation was characterized as G6PD Harilaou (F216L).[47,131] *Hb*, Hemoglobin.

TABLE 18-7 Clinical Spectrum of Chronic Nonspherocytic Hemolytic Anemia Caused by Severe Glucose-6-Phosphate Dehydrogenase Deficiency

Patients Studied	25 (All Male)
% with neonatal jaundice	100
% requiring exchange transfusion	24
% with splenomegaly	68

Lowest hemoglobin known, range (g/dL)	3.8-9.3
Reticulocytes, range (%)	3-51
% requiring multiple blood transfusion	72

than normal red blood cell size distribution curve. The red blood cell structure is mostly not characteristic, and for this reason it is referred to in the negative as being "nonspherocytic." The bone marrow shows normoblastic hyperplasia, unless the increased requirement for folic acid associated with the high red blood cell turnover has caused it to become megaloblastic. The patient has chronic hyperbilirubinemia, a decreased level of haptoglobin, and an increased level of lactate dehydrogenase. Hemoglobinuria is rare, but hemosiderinuria sometimes may be detected. The spleen is usually moderately enlarged in small children, and subsequently it may increase in size sufficiently to cause mechanical discomfort, hypersplenism, or both. Although most patients with CNSHA are diagnosed when they are children or young adults, patients have been known to be diagnosed in their fifties.[140]

Pathophysiology

The pattern of hemolysis in these patients is different from that described earlier for patients who have AHA associated with G6PD deficiency and instead is more reminiscent of the chronic hemolysis seen in persons with hereditary spherocytosis. However, oxidative stress caused by exposure to the same agents that cause AHA will cause acute exacerbation of hemolysis in persons with CNSHA. Unlike the situation in persons with thalassemia major, even in severe cases no evidence of ineffective erythropoiesis is found. The fact that no hemoglobinuria is present, at least in the steady state, suggests that the hemolysis is mainly extravascular and therefore that its mechanism is different from that of AHA. Studies of red blood cell membrane proteins have revealed the presence of high molecular weight aggregates[141,142] consisting largely of spectrin, which seem to make the membrane abnormally susceptible to shear-induced fragmentation.[143] These abnormalities in the red blood cells of G6PD-deficient patients with CNSHA are not found in asymptomatic G6PD-deficient subjects, thus suggesting that whereas in the latter group the reductive potential of residual G6PD is adequate in the steady state, in the former group, continuous oxidation of sulfhydryl groups takes place, followed by irreversible changes in the configuration of membrane proteins. The reason why the severity of CNSHA associated with G6PD deficiency is so variable is that almost every case is attributed to a different mutation (discussed later in this chapter) and each mutation will have a different effect on the stability of the enzyme, on its kinetic properties, or both. In exceptional cases, CNSHA has been seen in women: two heterozygotes (G6PD Volendam[144] and G6PD Tondela[145]) had an extremely skewed X-inactivation pattern favoring, paradoxically, the X chromosome with the abnormal G6PD allele. Two women have been genetic compounds for a polymorphic variant and a rare variant associated with CNSHA; they had evidence of chronic hemolysis but no anemia.[140]

Diagnosis

Laboratory diagnosis of G6PD deficiency is discussed next, but a special problem in relation to CNSHA is to firmly establish the causal link between G6PD deficiency and CNSHA. For example, if the patient is a Swede of Swedish ancestry or a Japanese person of Japanese ancestry, the link will be taken for granted, and this approach is generally justified, given the rarity of G6PD deficiency in these populations. On the other hand, if the patient is from a population in which G6PD deficiency is common, its presence in a patient with CNSHA might be a mere coincidence, and the cause of the CNSHA might be something else altogether. In such cases, while other causes of CNSHA are being ruled out, it becomes essential to characterize the G6PD of the patient. If it is a common variant known to be asymptomatic in other subjects, it can certainly be exonerated, whereas if it is a new unique variant, it is likely to be the culprit.

Treatment

In general terms, management of CNSHA that is associated with G6PD deficiency does not differ from that of CNSHA related to other causes (e.g., pyruvate kinase deficiency). If the anemia is not severe, regular folic acid supplements and regular hematologic surveillance suffice. It is important to avoid exposure to potentially hemolytic drugs, and blood transfusion may be indicated when exacerbations occur, mostly in concomitance with intercurrent infection. In rare patients, the anemia is so severe that it must be regarded as transfusion-dependent. In these cases blood transfusion will be probably needed at approximately 2-month intervals to keep the hemoglobin in the 8 to 10 g/dL range. A hypertransfusion regimen aiming to maintain a normal hemoglobin level is not indicated because there is no ineffective erythropoiesis in the bone marrow. However, depending on the extent of the blood transfusion requirement, appropriate iron chelation should be instituted from the age of 2 years onward and must be continued as long as transfusion treatment is necessary (the transfusion requirement may sometimes decrease after puberty).

A special problem is that of splenectomy.[69] No evidence exists of selective red blood cell destruction in the spleen, as in hereditary spherocytosis. However, the fact that the spleen is usually enlarged suggests that its role in hemolysis is not negligible. In practice, the following three indications exist for splenectomy: (1) if splenomegaly becomes a physical encumbrance; (2) if the patient exhibits evidence of hypersplenism; and (3) if the anemia is severe, even in the absence of the first two indications. A splenectomy may reduce the overall rate of hemolysis (see Fig. 18-9) just enough to make a transfusion-dependent child become transfusion-independent.[146] Becoming transfusion-independent is doubly important because it makes it possible to dispense with iron chelation. Active immunizations before a splenectomy and penicillin prophylaxis after a splenectomy must be started as indicated by guidelines such as those produced by the British Committee for the Standards in Haematology (http://onlinelibrary.wiley.com/doi/10.1111/j.1365-2141.2011.08843.x/pdf).

When a diagnosis of CNSHA is made, genetic counseling must be provided to the family, and it is advisable to establish whether the mother is a heterozygote. If she is a heterozygote, the chance of recurrence is 1 : 2 for every subsequent male pregnancy. Prenatal diagnosis should be offered; although it could be carried out on amniotic fluid cells, it would be much preferable to determine the mutation involved and test for it on DNA from chorionic villi.[147] G6PD-deficient patients with severe CNSHA (see Fig. 18-9)—because their clinical manifestations are limited to blood cells—would in principle be good candidates for gene therapy by gene transfer into hematopoietic stem cells. This approach has not yet reached the stage of clinical application, but preclinical experiments have been carried out successfully in mice[148] and rhesus monkeys.[149]

LABORATORY DIAGNOSIS OF G6PD DEFICIENCY

The final diagnosis of G6PD deficiency must rely on an enzyme essay, which is fortunately easy to perform, and numerous "screening tests" can be used as substitutes if a spectrophotometer is not available. However, a number of potential pitfalls and sources of error must be understood, and the use of commercial kits is not a substitute for such understanding.

Tests for G6PD Deficiency

The classic spectrophotometric method[150] directly measures the rate of formation of NADPH through its characteristic absorption peak in the near-ultraviolet spectrum at 340 nm. Red blood cell activity is expressed in international units (micromoles of NADPH produced per minute) per gram of hemoglobin; therefore it is best to assay the enzyme activity and the hemoglobin concentration in the same hemolysate and work out the ratio. Because G6PD activity is much higher in leukocytes (particularly in granulocytes) than in erythrocytes, for accurate measurements it is essential to remove all leukocytes by using the Ficoll-Hypaque method or by filtration through cellulose powder[151] rather than by using the cruder approach of sucking off the buffy coat; however, for the purpose of clinical diagnosis of G6PD deficiency, it is not strictly necessary to remove all leukocytes. In normal red blood cells, the range of G6PD activity, measured at 30° C, is 7 to 10 international units/g of hemoglobin.

Several "screening tests" for G6PD deficiency are useful and reliable provided they are run properly and their limitations are understood. The dye decolorization test[152] and the methemoglobin reduction test[153] are not used much anymore; a fluorescence spot test[151] and a formazan-based spot test[154] are available, and the latter has been field tested.[155] All these methods are semiquantitative and are meant to classify a sample simply as "normal" or "deficient." The cutoff point can be set by following the appropriate instructions and by trial and error in the individual diagnostic laboratory. One should aim to classify as deficient any sample having less than 30% of normal activity, because above this level it is unlikely that serious clinical manifestations will occur. Screening tests are of course especially useful for testing large numbers of samples. They are also perfectly adequate for diagnostic purposes in patients who are in the steady state but *not* for patients in the posthemolytic period or with other complications; in addition, they cannot be expected to identify all heterozygotes. Finally, an ideal screening test ought not to give "false-negative" results (i.e., it should not misclassify a G6PD-deficient subject as normal), but it can be allowed to give a few "false-positive" results (i.e., a G6PD-normal subject might be misclassified as being deficient in G6PD). Ideally, in every patient found to be deficient in G6PD by screening, the finding should be confirmed with a spectrophotometric assay.

The Effect of Red Blood Cell Age and Selective Hemolysis

Because G6PD decreases gradually as red blood cells age,[64] any condition associated with reticulocytosis will entail an *increase* in G6PD activity (Table 18-8), which means that if a subject is genetically G6PD normal, in the course of hemolysis, red blood cell G6PD activity will now be *above* the normal range. This situation does not affect the diagnosis because G6PD deficiency will be correctly ruled out. However, if the subject is genetically G6PD deficient, red blood cell G6PD may now be raised to the extent of being near or even within the normal range, and the patient might therefore be misclassified as being G6PD normal[156] (even though at the onset of the attack the level may have been low).[157] Thus after a hemolytic attack, two circumstances occur to cause a risk of misdiagnosis: first, the older cells have been destroyed selectively, and second, the marrow response has caused a sudden outpouring of young cells into the peripheral blood. (A third confusing factor may be admixture of G6PD-normal red blood cells if the patient has undergone a transfusion.) Although the reticulocyte count is a good warning to avoid this mistake, it must be realized that because reticulocytes turn into morphologically "mature" erythrocytes within 1 to 2 days, their count is not a sensitive index of mean red blood cell age; in other words, mean red blood cell age may be significantly younger than normal even when the reticulocyte count is normal. These problems may be circumvented in several ways. First, a G6PD level in the low-normal range (as opposed to higher than normal) in the presence of reticulocytosis is always suspicious; indeed, this finding suggests that the patient is actually G6PD deficient. Second, if the

TABLE 18-8 Red Blood Cell Glucose-6-Phosphate Dehydrogenase Levels in Various Clinical Situations

Clinical Condition	Gender	Result of Screening Test	Result of G6PD Assay	Interpretation

Chronic hemolysis	M	Abnormal	1.4	CNSHA, probably caused by G6PD deficiency

AHA, Acute hemolytic anemia; *CNSHA,* congenital nonspherocytic hemolytic anemia; *G6PD,* glucose-6-phosphate dehydrogenase.

patient is experiencing or recovering from AHA, the suspicion generated from the finding just mentioned can be simply kept in store for a few weeks, when the situation will be evolving toward the steady state, and a repeat test will prove whether the patient is indeed deficient in G6PD. Third, if either the urgency of some clinical decision or academic curiosity demands a more prompt solution of the problem, the presence of severely G6PD-deficient red blood cells can be demonstrated either by an enzyme assay of the oldest cells (fractionated by sedimentation) or by a cell-based methodology (described later).

G6PD Deficiency in Heterozygotes

For special purposes, formazan-based cytochemical methods are also available.[158,159] For hemolysis to be clinically significant in heterozygous girls, at least 50% of the red blood cells must be deficient, and therefore the G6PD level will be about 50% of normal or less. This level of deficiency can be diagnosed by a quantitative test; however, the problems associated with current or recent hemolysis outlined for male patients will be compounded in the case of heterozygous females, and they can usually be overcome by a similar approach, particularly with the use of a cytochemical test. A different matter is the biologic diagnosis of heterozygosity, regardless of immediate clinical implications, as may sometimes be required for appropriate genetic counseling. In cases of “extreme phenotypes” (sometimes referred to as arising from “imbalanced lyonization”), the G6PD-deficient red blood cells may be so few that the only way to identify heterozygous G6PD deficiency will be by DNA analysis: for this approach the underlying mutation must be known. Recently, based on methemoglobin reduction,[153] a cytofluorometric G6PD assay has been developed,[160] which ought to be ideal for assessing the phenotype of heterozygotes. A special situation involves heterozygotes for G6PD variants associated with CNSHA. In our experience, the mothers of (male) patients with this condition are often G6PD normal, either because the variant in the offspring is due to a de novo mutation[53] or because the mother is a heterozygote but is phenotypically normal, presumably because somatic selection has favored the hematopoietic progenitor cells with the normal G6PD allele.[50]

Molecular Analysis of the G6PD Gene

Because mutation analysis at the DNA level is currently easy, and because in many populations one knows which mutations are most common, it may be tempting to adopt this approach and to bypass a G6PD assay altogether. This approach is fine as long as a known mutation is found; however, if it is not found, it may be that the patient in question has an unexpected mutation, in which case it would be unsafe to presume that the patient is G6PD normal. On the other hand, in special cases (see the previous section for heterozygote diagnosis), and particularly in the case of CNSHA, identification of mutations with reference to the large numbers of mutations already known (see the Human Gene Mutation Database at http://www.hgmd.cf.ac.uk/ac/gene.php?gene=G6PD) is recommended, and it could also discover new mutations. Of course, it may not be long before complete sequencing of all exons and intron-exon junctions may be sufficiently inexpensive to become routine.

GENOTYPE-PHENOTYPE CORRELATIONS

A rigorous definition of a polymorphic allele is one with a frequency higher than can be accounted for by recurrent mutation; however, for convenience, a conservative practical criterion is any allele with a frequency of at least 1% in at least one population. According to this criterion, 26 well-mapped *Gd* polymorphic alleles have already been identified (see Figs. 18-4, *B*, and 18-5).[68] The ratio of subjects having G6PD deficiency associated with CNSHA to those having “simple” G6PD deficiency varies in different populations. For instance, in Japan, where G6PD deficiency is on the whole very rare, the majority of patients with G6PD deficiency have been reported to have CNSHA.[161] This finding suggests that CNSHA that is caused by rare sporadic variants, many of which may result from recent mutations, reflects the intrinsic mutation rate of the human *Gd* gene, which is likely to be uniform throughout the world; in contrast, “simple”

G6PD deficiency almost always results from common variants that have arisen many generations ago and spread through biologic selection.[68]

The three variants mentioned previously—G6PD A, G6PD Mediterranean, and G6PD Mahidol—are probably those for which clinical expression has best been characterized.[162] Although G6PD A is often quoted as having fewer clinical manifestations than the others, the differences are marginal, and they are unlikely to be relevant with respect to patient management. The severity of hemolysis and whether it is "self-limited" probably depend on the offending agent, its dose, and the time course of exposure more than it depends on the G6PD variant involved. Notably, favism has been unambiguously documented with G6PD A–.[163,164,165]

In terms of clinical expression, the demarcation between class I variants and all others is, by definition, much more clear-cut. Indeed, one of the outstanding questions in the biochemical genetics of G6PD is why a particular variant can cause CNSHA rather than just AHA. In certain cases the level of residual enzyme activity is not the whole answer because qualitative differences are also important, as first suggested by Kirkman and Riley.[166] The most likely way in which a structural change can significantly alter the function of G6PD, *given the same level of deficiency*, is by affecting the binding of one of the main ligands (i.e., G6P, NADP, and NADPH). For instance, G6PD Mediterranean and G6PD Coimbra both have mutations near the G6P binding site, and both have *increased* affinity for G6P. Perhaps because of this characteristic, although they are both severely deficient, they belong to class II and not to class I. G6PD Orissa, the main polymorphic variant in tribal Indian populations,[74] also belongs to class II despite having *decreased* affinity for NADP. Thus the affinity for G6P appears to be of greater importance. Indeed, comparison of the distribution of K_m^{G6P} values of class I variants with that of class II and III variants shows that they are significantly lower in the latter group.[8]

However, in most cases the main factor responsible for causing CNSHA is a very low level of residual activity in red blood cells, which in turn is due to marked in vivo instability. It is quite remarkable that although G6PD mutations as a whole are evenly spread throughout the gene's coding sequence, the majority of class I mutations are clustered in exons 10 and 11 (see Fig. 18-4, *B*). The three-dimensional model of the human G6PD dimer has, at long last, provided a reasonable explanation for this finding.[68,167] Indeed, these two exons encode the protein region that constitutes the interface between the two identical subunits of the enzyme. As a result, any mutation in this region causes the respective amino acid replacements in the two subunits to be quite near each other in the dimer structure, thus potentially increasing their deleterious effects. Even more important, because no covalent link exists between the subunits, it stands to reason that any interference in the shape of the interface surfaces may affect their mutual fit and therefore dramatically destabilize the active form of the enzyme. Defects in protein folding have been studied in detail for certain G6PD variants.[168,169]

G6PD DEFICIENCY AND PREVENTIVE MEDICINE

Because NNJ and AHA are the most common manifestations of G6PD deficiency, it is most important to consider how they can be prevented. The first step is to identify G6PD-deficient persons, which is where screening is most pertinent. Of course, whether population-wide screening is both desirable and feasible depends primarily on the prevalence of G6PD deficiency in any particular community, which will determine the cost-benefit ratio. For instance, there has been experience with screening in Sardinia[170] and Malaysia,[171] and recently screening has been considered as a possibility in the United States.[115] If screening is performed at all, it is best performed with cord blood. Once a person is known to be G6PD deficient, the two main implications are the risk for NNJ and the importance of avoiding exposure to agents that can cause AHA. NNJ cannot be prevented as yet, but awareness of G6PD deficiency must entail surveillance for NNJ until at least day 4 and special recommendations with respect to factors such as naphthalene that can cause it or make it worse. By contrast, at least one type of AHA—namely, favism—is completely preventable (Fig. 18-10). Prevention of infection-induced hemolysis is obviously more difficult. Prevention of drug-induced hemolysis is possible in most cases by choosing alternative drugs, but that may be difficult when none is available. The most common problem is the need to administer primaquine for the eradication of malaria caused by *Plasmodium vivax* or *Plasmodium malariae*. In these cases, administration of a lower dosage for a longer time is the recommended approach. Hemolysis will still occur, but under appropriate surveillance it will be of an acceptably mild degree.

A special problem in prevention is what to do about new drugs, the hemolytic potential of which is unknown. Although in vitro methods to test drugs in this respect do exist,[172,173] such tests are unfortunately not routinely carried out before drugs are released on the market, and thus their hemolytic potential will become apparent only as a result of clinical observation. Recently a combination of dapsone and chlorproguanil that was used as an antimalarial agent in several African countries[174,175] was withdrawn from the market because of life-threatening hemolytic complications.

G6PD DEFICIENCY IN NONERYTHROID CELLS

As mentioned earlier, because nucleated somatic cells have the capability to synthesize G6PD constitutively, they are affected by G6PD deficiency to a lesser degree than are red blood cells.[176] For instance, subjects with G6PD Mediterranean have less than 5% G6PD activity in red blood cells but about 30% of normal in granulocytes, whereas subjects with G6PD A– have about 12% G6PD activity in red blood cells but nearly normal activity in granulocytes. On the other hand, if deficiency results from a drastic change in catalytic efficiency or in substrate affinity, deficiency may be more universal. In practice, the only well-documented pathologic effect is expressed in granulocytes. Very few of the class I G6PD

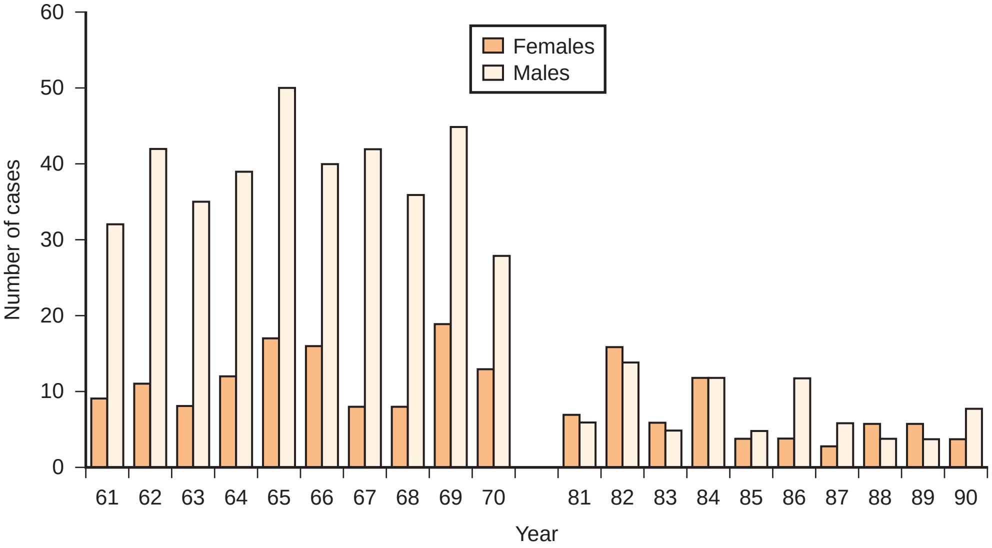

Figure 18-10 Control of favism in a community. The data show the decrease in the number of yearly admissions for favism in the children's department of the main city and university hospitals in Sassari, northern Sardinia. During the 10-year period intervening between the two sets of data, two preventive measures were adopted: (1) education through the media and (2) screening of all newborns for glucose-6-phosphate dehydrogenase (G6PD) deficiency. Note the dramatic reduction in the incidence of favism in boys and the more modest decrease in girls. The data suggest that (1) preventive measures are effective; (2) the increased proportion of girls can be attributed to failure of the screening method used to pick out many of the heterozygotes; and (3) in view of (2), the dramatic reduction observed in boys can perhaps be credited to screening more than to the educational campaign. *(Courtesy of Professor Tullio Meloni, Sassari, Sardinia.)*

variants cause not only CNSHA but also granulocyte dysfunction, mainly in the manner of impaired killing of phagocytosed bacteria (an example is G6PD Barcelona).[177] Patients with these variants have increased susceptibility to bacterial infection, particularly with *Staphylococcus aureus*. Recently, in a group of patients who sustained major trauma in road traffic accidents, Spolarics et al. (2001)[107] made the interesting observation that the frequency and severity of infection were significantly higher in patients who were deficient in G6PD. Thus neutrophil function may be affected in extreme situations, even in persons with the common type of G6PD deficiency (the patients in the clinical study all had G6PD A–). The mechanism whereby G6PD deficiency impairs phagocytosis is a defect of the oxidative burst caused by a shortage in NADPH supply, similar to that observed in chronic granulomatous disease, in which one of the components of the cytochrome b_{245} system is defective.[178] Functional abnormalities have also been demonstrated in macrophages from G6PD-deficient mice.[179]

Erythrocytes are not the only nonnucleated cells in the body. Another example is in the eye lens, and juvenile cataracts have been reported occasionally in subjects with G6PD deficiency.[180,181] Whether G6PD deficiency is more generally associated with a higher frequency or earlier onset of cataracts still appears to be controversial.[182-185]

G6PD DEFICIENCY COEXISTING WITH OTHER DISORDERS

In areas where G6PD deficiency is common, it is not infrequent that it may be encountered in the same patient together with another hematologic or nonhematologic condition.

Association with Other Hematologic Diseases

The combination of G6PD deficiency with the sickle cell trait has been no more frequent than could be expected by chance.[186,187] Several studies have shown that no significant differences exist in a variety of clinical and hematologic parameters between two otherwise comparable groups of patients with sickle cell anemia (SCA), those with and those without G6PD deficiency.[156,188-190] It has been reported that G6PD deficiency is associated with increased cerebral blood flow velocity[191] in children with SCA, but this finding has not been confirmed by other investigators,[192] and a significantly increased risk of stroke does not appear to exist.[193] Overall, G6PD deficiency does not seem to make much difference to SCA in the steady state; however, acute intravascular hemolysis that can occur in G6PD-deficient patients must be regarded as more dangerous when it is superimposed on the chronic hemolytic anemia of SCA. The combination of G6PD deficiency with the β-thalassemia trait has been found to cause a significant increase in mean corpuscular volume,[194] which nonetheless remains below the normal range. Association of G6PD deficiency with thalassemia major is unlikely to be a problem because patients with the latter condition are treated with regular blood transfusions or with bone marrow transplantation. However, the association may be significant in patients with various forms of thalassemia intermedia syndromes (e.g., hemoglobin E-β-thalassemia).[195]

Occasionally G6PD deficiency has been observed in association with much rarer red blood cell abnormalities, such as pyruvate kinase deficiency,[196,197] congenital dyserythropoietic anemia type II,[198-200] and hereditary elliptocytosis.[201] In these cases the two abnormalities seem to produce only additive clinical effects, but in at least one family, G6PD deficiency was synergistic with hereditary spherocytosis in causing moderately severe chronic hemolytic anemia.[202]

Association with Nonhematologic Diseases

Several studies have reported variable degrees of association between diabetes and G6PD deficiency,[203-209] and various underlying mechanisms have been hypothesized.[210,211] In the course of diabetic decompensation, AHA may develop in G6PD-deficient patients with diabetes[212,213]; on the other hand, downregulation of G6PD has been reported in some West African patients with type 1 diabetes who are predisposed to ketoacidosis.[214] The prevalence of proliferative retinopathy may be increased in G6PD-deficient patients with type I diabetes.[215] In the area of eye disease, it has also been reported that G6PD deficiency is a risk factor for the development of pterygium.[216] Apart from the fact that hepatitis can precipitate hemolysis in G6PD-deficient children, ribavirin, which is now often used in the treatment of hepatitis C, can itself cause hemolytic anemia (regardless of whether the patient is deficient in G6PD). On the other hand, it has recently been shown that G6PD-deficient patients with hepatitis C can be treated safely with ribavirin and pegylated interferon.[217] During the past few years extensive studies have been performed with regard to the influence of G6PD deficiency on cardiovascular physiology and pathology and even cardiac surgery.[218-220]

Recently a unique case has been reported of a Turkish child who has co-inherited the rare condition hypohidrotic ectodermal dysplasia, together with G6PD deficiency, on the same X chromosome.[221]

Trauma and G6PD Deficiency

Although G6PD deficiency protects against malaria, some reports indicate that it worsens the clinical course of traumatic patients.[202] Altered cytokine response would be the underlying pathogenetic mechanism predisposing to infections in G6PD-deficient persons.[222]

G6PD-Deficient Donors

Thousands of units of G6PD-deficient blood have been used in blood transfusion practice without problems. However, for babies with NNJ, it is advisable to test donor blood and to only use blood with a normal level of G6PD.[223] G6PD-deficient subjects have also served as bone marrow transplant donors; the recipient has, of course, become G6PD deficient, but engraftment has been normal.[224]

G6PD POLYMORPHISM AND MALARIA

The striking correlation between the worldwide distribution of G6PD deficiency (see Fig. 18-5) and that of *Plasmodium falciparum* prompted formulation of the "malaria hypothesis" half a century ago.[225,226] Since that time numerous more detailed epidemiologic studies (which can be referred to as "micromapping"),[227] as well as clinical studies,[228] have supported the notion that G6PD deficiency confers some degree of resistance to the potentially lethal malaria parasite *P. falciparum* and that in malaria-endemic areas, G6PD alleles associated with enzyme deficiency have therefore been subjected to positive darwinian selection.[229-231] A geographic correlation certainly does not amount to proof, but four large clinical studies carried out in Africa have tested the malaria hypothesis directly in the field. Although it is puzzling that in two of these studies[232,233] increased resistance to the parasite was significant only in heterozygous females, in one study[234] a protective effect was seen in both males and females, and in another study[235] a protective effect was noted only in males. All four studies concur in supporting the notion of malaria selection for G6PD deficiency. As for the mechanism of this phenomenon, in vitro studies have shown that invasion of G6PD-deficient red blood cells by *P. falciparum* takes place normally, but parasite growth is affected by previous passage through G6PD– cells.[236] On the other hand, parasitized red blood cells are recognized more promptly by macrophages when they are G6PD deficient[237]; thus accelerated removal of parasitized red blood cells (suicidal infection)[238] may be the most important mechanism of protection, as it is for subjects with the sickle cell trait.[239] An additional strong argument in favor of malaria selection is the genetic heterogeneity of polymorphic *Gd*$^-$ alleles in itself. Indeed, each one of these alleles, having arisen through an independent mutational event, must have increased in frequency on its own in a particular geographic area[240] where malaria was or still is endemic—a good example of convergent evolution driven by the same selective force.[241] Recent work from Thailand suggests that G6PD deficiency may confer resistance not only against *P. falciparum* but also against *P. vivax*.[242]

CHAPTER 19

Normal and Abnormal Hemoglobins

Christopher S. Thom, Claire F. Dickson, John S. Olson, David A. Gell, and **Mitchell J. Weiss**

CHAPTER OUTLINE

HEMOGLOBIN STRUCTURE AND FUNCTION
Hemoglobin Primary Structure
Hemoglobin Secondary Structure
Hemoglobin Tertiary Structure
The Prosthetic Heme Group
Hemoglobin Quaternary Structure
Dioxygen Binding
Redox Reactions of Hemoglobin
Ineffective Erythropoiesis in Thalassemia
ABNORMAL HEMOGLOBINS
Introduction to Hemoglobin Variants
Identification of Hemoglobin Variants
Clinical Manifestations of Hemoglobin Variants Reflect Their Physiological Effects
Ontogeny of Globin Gene Expression Influences the Clinical Presentation of Hemoglobin Variants
Clinical Laboratory Tests to Identify Hemoglobin Variants
Clinical Management of Patients with Hemoglobin Variants
Pathophysiology of Hemoglobin Abnormalities
CONCLUSION

Studies of hemoglobin (Hb) structure, function, and expression over more than 50 years have produced many paradigms in biology and medicine. The first part of this chapter describes the structural and biochemical properties of Hb, emphasizing those that underlie its physiological roles. The conserved globin protein fold with the heme prosthetic group confers the basic function of reversible oxygen (O_2) binding, which is common to myoglobin (Mb), Hb, and numerous other recently discovered proteins such as neuroglobin and cytoglobin. The tetrameric quaternary structure of Hb allows for cooperative O_2 binding to achieve efficient loading of O_2 in lung capillaries at high partial pressure of O_2 (P_{O2} ≈100 mm Hg), and effective O_2 delivery to peripheral tissues at low P_{O2} (≈40 mm Hg). Several small molecules, including 2,3-diphosphoglycerate (2,3-DPG), chloride anion (Cl^-), and carbon dioxide (CO_2)/bicarbonate dynamically regulate O_2 binding to Hb in response to varying physiological conditions. Hb also facilitates transport of CO_2 in the form of bicarbonate anion and participates in oxidation reactions, both beneficial and deleterious. The second part of this chapter reviews the biochemistry and pathophysiology of abnormal Hbs that give rise to human diseases. Globin gene mutations that alter the properties of Hbs are common, affecting about 7% of the world's population,[1,2] and present a significant global health problem.[3]

This chapter reviews Hb structure, biochemistry, and mutations that produce abnormal globin proteins. These "Hb variants" are usually caused by single amino acid substitutions, but also by amino acid insertions and/or deletions, antitermination mutations and altered post-translational processing. The most common pathological Hb variants, HbS and HbC are reviewed in Chapter 20. Other variants, discussed in the second part of this chapter, number more than a thousand and are rare individually but common collectively. Globin gene mutations that impair protein subunit production (i.e., thalassemias) are discussed in Chapter 21. Several excellent references review the concepts discussed in this chapter.[4-12,13]

HEMOGLOBIN STRUCTURE AND FUNCTION

The study of Hb and related proteins has contributed immensely to the understanding of protein function in general. In 1957, Kendrew and colleagues used X-ray diffraction to solve the structure of Mb at 6-Å resolution[14] and a few years later refined this structure to 2 Å, making it possible to build models at near atomic resolution.[15] These remarkable achievements showed for the first time what a protein actually "looks like." Almost simultaneously the structure of Hb was determined at 5.5-Å resolution by Perutz and colleagues.[16] Since then numerous biophysical studies have further refined the structures of normal and mutant Hbs to resolutions approaching 1 Å.[17]

HbA, the major adult form of Hb, is a tetramer of two α polypeptide chains and two β polypeptide chains ($\alpha_2\beta_2$),

Box 19-1 Hemoglobin Structure

- The globin fold is an evolutionary conserved structure made up of seven or eight α helices folded into a globular shape.
- HbA is a tetramer made up of two α- and two β-globin subunits, each linked to a heme moiety that binds O_2 reversibly via a central iron molecule. Only reduced iron (Fe[II]) can bind O_2.
- Hb can bind other diatomic ligands via heme iron, including CO and NO.
- The α1β1 (and α2β2) dimer is the basic structural unit of hemoglobin.
- Various α- and β-like globins are expressed during human ontogeny. These include:
    - Embryonic: Gower 1 ($\zeta_2\varepsilon_2$), Gower 2 ($\alpha_2\varepsilon_2$), Hb Portland I ($\zeta_2\gamma_2$), Hb Portland II ($\zeta_2\beta_2$)
    - Fetal: HbF ($\alpha_2\gamma_2$)
    - Adult: HbA ($\alpha_2\beta_2$), ~95%; HbA_2 ($\alpha_2\delta_2$), 1.5%-3.5%; HbF ($\alpha_2\gamma_2$), 1%-2%.

each bound to a heme prosthetic group (Box 19-1). The α and β globins are believed to have arisen from the duplication of a common ancestral gene approximately 450 million years ago,[18] around the time that the lineages of cartilaginous fish and bony fish diverged. Subsequent gene duplications produced additional globin genes that are expressed at different times during ontogeny. During early human embryogenesis, the α-like (ζ) and β-like (ε and γ) chains produce embryonic Hbs ($\zeta_2\varepsilon_2$, $\zeta_2\gamma_2$, and $\alpha_2\varepsilon_2$). During midgestation, fetal Hb (HbF; $\alpha_2\gamma_2$) is predominantly expressed. From birth until around postnatal week 12, β-globin expression gradually increases and γ globin decreases as HbA replaces HbF. Another β-like globin (δ) is also expressed postnatally, and normal hemolysates contain approximately 2% HbA_2 ($\alpha_2\delta_2$). The properties of embryonic and fetal globins are tuned to the physiological conditions experienced in utero, particularly low O_2 tension, although the functions of all human Hb isoforms can be understood as variations on the mechanism of adult HbA. The onset of symptoms caused by deleterious globin gene mutations varies according to the developmental expression pattern of each particular gene, as discussed later in this chapter.

Hemoglobin Primary Structure

Primary structure refers to the linear sequence of amino acids within a protein. The primary structures of the α-like and β-like globin chains are shown in Table 19-1. Translation of the polypeptide chains on the ribosome is initiated with methionine, which is subsequently removed by methionine aminopeptidase before assembly of mature Hb tetramer. The α (141 amino acid residues) and β (146 amino acid residues) chains share only 41% amino acid

From Bunn HF, Nagel RL: Hemoglobins: normal and abnormal. In Nathan DG, Orkin SH, Ginsburg D, et al, editors: Nathan and Oski's hematology of infancy and childhood, *vol 7, Philadelphia, 2009, Saunders, p. 911–948; and modified from Bunn HF, Forget BG:* Hemoglobin: molecular, genetic, and clinical aspects, *Philadelphia, 1986, Saunders.*

*The α and α-related (ζ) subunits are shown at the left. The β and β-related (δ, γ, and ε) chains are at the right. The amino acids' relationship to the eight globin helices (A to H) is also shown. Thus A16 is the sixteenth amino acid in the A helix. Interhelical elbows are named for the two adjacent helices (e.g., AB1 is the first amino acid between helices A and B). The N- and C-terminal residues are labeled NA and HC, respectively. The residues are aligned to maximize the homology between subunits, which causes some gaps.

sequence identity, yet they adopt very similar three-dimensional (3D; tertiary) structures. Numerous naturally occurring mutations alter the primary sequence of globin proteins[12,13] (see the second part of this chapter).

Hemoglobin Secondary Structure

Secondary structure refers to the organization of primary structure into sections of regular polypeptide backbone geometry. Hb chains are comprised primarily of α-helical secondary structure joined by turns or short sections with irregular polypeptide backbone conformation. The geometry of regular secondary structure is dictated by steric constraints (clashes between atoms in neighboring residues) and maximization of hydrogen bonding between amide and carbonyl groups in the backbone. Although hydrogen bonds are relatively weak individually, their repeating pattern in α helices has a cooperative effect to make the structure comparatively rigid. Through this property, α helices transmit forces in proteins and protein complexes to alter their structure and modulate function, as occurs for Hb. Most globin chains contain seven or eight α helices labeled *A* through *H* (from amino to carboxyl terminus), with the intervening links referred to as *corners* or *loops*. The position of each residue is described with reference to these structural elements. For example, the heme-coordinating histidine occurs at position F8 (residue 8 in helix F) in all globins (see Table 19-1).

Hemoglobin Tertiary Structure

Tertiary structure refers to the 3D structure of a polypeptide that is formed by packing secondary structural elements together. In general, hydrophobic side chains occupy the interior of a protein or protein domain, and polar and charged residues are arranged on the exterior (Fig. 19-1, *A* and *B*). Thus mutations converting a nonpolar interior amino acid to a polar one commonly produce an unstable protein (see the second part of this chapter). The α-helical segments of globin chains fold together into a globular shape with a cavity that is occupied by the O_2-binding heme prosthetic group[16,17] (see Fig. 19-1, *B*-*D*). The basic tertiary structure, called the *globin*

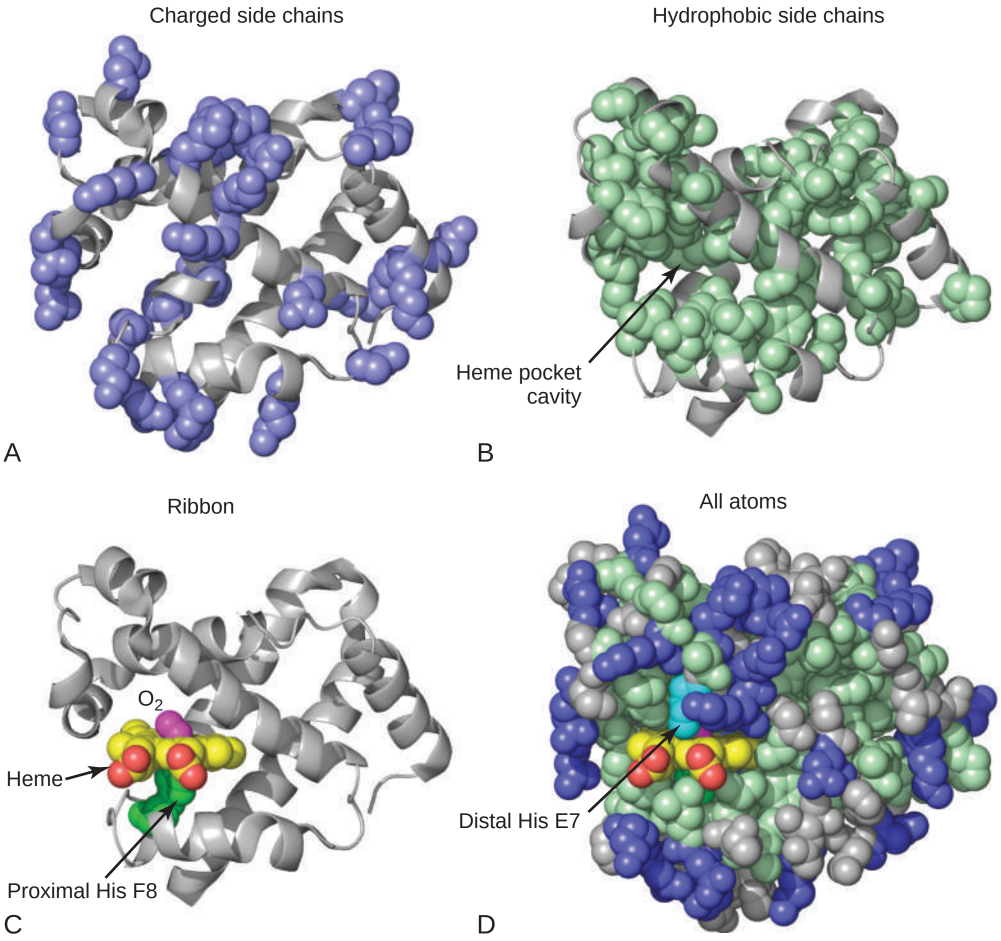

Figure 19-1 The secondary structure and amino acid composition of the β chain of Hb. **A**, Charged side chains (*blue*: Lys, Arg, Glu, Asp) are all located on the surface of the structure exposed to the polar solvent (water). His side chains can be charged or uncharged depending on solvent and local protein environment and are not shown. **B**, Hydrophobic (nonpolar) side chains (*pale green*: Ala, Val, Leu, Ile, Pro, Met, Phe, Trp) are clustered in the center of the structure, forming a hydrophobic core. Other polar, uncharged residues are not shown. **C**, A ribbon diagram showing the eight α helices, the location of the heme group *(yellow/red spheres)*, heme-coordinating proximal His *(green)*, and bound O_2 *(magenta)*. **D**, All atoms showing how O_2 *(magenta)* is buried in the heme pocket and stabilized by distal His E7. Rotation of the distal His E7 side chain is required to allow O_2 entry/exit from the distal heme pocket.

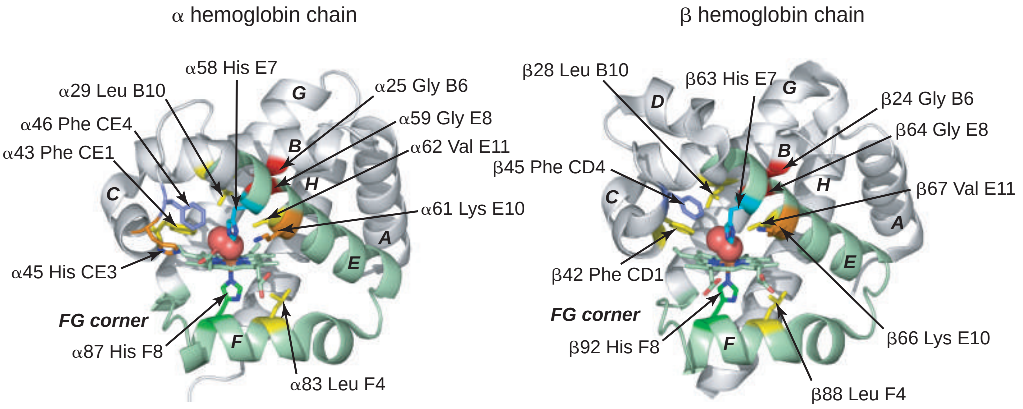

Figure 19-2 Structural features of the globin fold. Ribbon representations of the α and β Hb chains in the O_2-bound form, with the α helices A–H in the β chain and A–C and E–H in the α chain labeled. Note the conserved tertiary structure of the two globin subunits. Conserved residues in α and β are shown in stick representation, and carbon atoms are colored according to their function as follows. The proximal His F8 *(green)* coordinates the heme iron. The distal His E7 *(cyan)* makes electrostatic interactions that stabilize bound O_2 *(red spheres)*. Hydrophobic side chains in the distal heme pocket *(yellow)* make steric interactions with O_2 and other diatomic ligands. Hydrophobic Leu F4 prevents water from entering the proximal heme pocket and disrupting the His F8–Fe bond.[26] Hydrophobic αPhe CE1/βPhe CD1 make important stabilizing interactions with the heme, help orient bound O_2, and together with αPhe CE4/βPhe CD4 help position the distal His E7. Basic side chains *(orange)* interact with the negatively charged propionates of the heme group. The small side chains of Gly E8 and Gly B6 *(red)* are required to allow close packing of the E and B helices. Upon O_2 binding, tertiary structural changes in the globin chains are most significant in helices E and F and in the FG corner, which together with the heme group form the “allosteric core” *(pale green)*.

fold, occurs in a large, ancient protein family with members expressed in animals, plants, and bacteria.[19,20] Figure 19-2 shows the tertiary structures of α and β globin with conserved α-helical arrangements and amino acid residues that mediate Hb function. Importantly, these structures are not static or rigid. Rather the tertiary structures of α and β globins (and the quaternary structure of the tetramer) change according to binding of O_2 or other ligands and also through interactions with allosteric effectors. These dynamic structural properties underlie the physiological function of Hb as a gas transporter and the pathologic features of many Hb variants.

The Prosthetic Heme Group

Each α and β chain binds one heme b group (Fig. 19-3), which forms the binding site for O_2 (see Fig. 19-1, C). Heme is an amphipathic molecule that is highly insoluble in water, so it must be bound to protein carriers or protein active sites under physiologic conditions. Biosynthesis of protoporphyrin IX occurs through eight well-characterized steps that take place either in the cytosol or the intermembrane space of mitochondria.[21] The final step, insertion of an iron ion, is catalyzed by the enzyme ferrochelatase.[21]

In the folded α and β chains, heme is bound into a deep pocket that is lined with hydrophobic residues (see Fig. 19-1, *B* and *D*). Interactions between the protein and heme are critical for stabilizing the native globin fold.[22-25] Thus mutations that destabilize heme–protein interactions lead to increased globin precipitation and the release of free heme, which has pathologic consequences (see the second part of this chapter). A coordinate covalent bond between the heme iron and the Nε atom of a histidine residue in the co-factor binding pocket, termed the *proximal histidine (F8)*, is of primary importance for globin

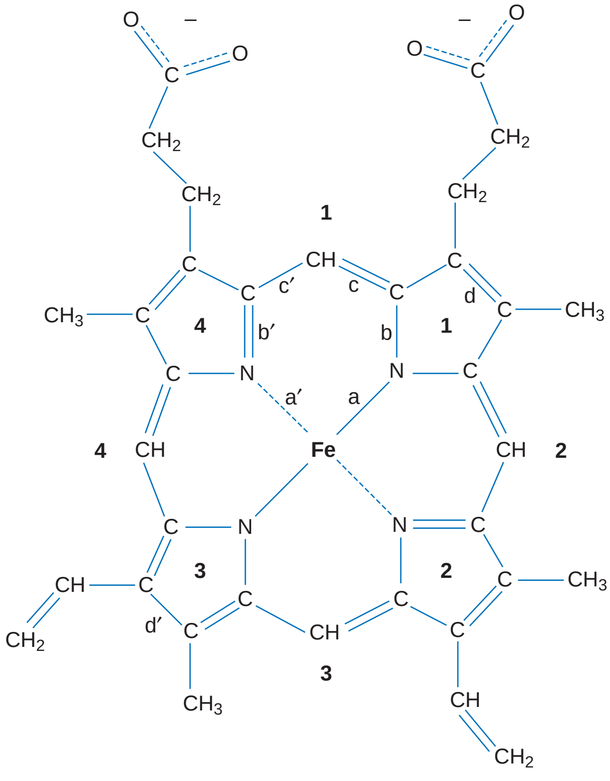

Figure 19-3 The heme group. The chemical structure of heme b, Fe(II)–protoporphyrin IX. The organic component, protoporphyrin IX, is a conjugated system of four pyrrole rings joined by methene bridges, with four methyl, two vinyl, and two propionate side chains. A central iron, the O_2-binding molecule in Hb, is coordinated in a square-planar arrangement by lone pairs from the four pyrrole nitrogens. *(From Bunn HF, Nagel RL: Hemoglobins: normal and abnormal. In Nathan DG, Orkin SH, Ginsburg D, et al, editors:* Nathan and Oski’s hematology of infancy and childhood, *vol 7, Philadelphia, 2009, Saunders, p. 911–948.)*

structure and O_2 binding function (see Fig. 19-1, *C* and Residues of the Heme Pocket). A sixth iron–coordination site on the opposite (distal) side of the planar heme is available for reversible O_2 binding (see Fig. 19-1, *C*). In addition to direct iron coordination to the proximal histidine, the following heme–globin interactions are important for maintaining the Hb tertiary structure: 1) hydrophobic interactions between nonpolar residues in the pocket and the porphyrin ring; 2) hydrogen bonding between residues in the distal heme pocket and diatomic ligands; and 3) electrostatic interactions between the heme propionates and amino acids on the surface of the protein.[22,26-28] An asymmetric distribution of methyl and vinyl side groups on the heme ring defines a stereospecific orientation of heme binding. Heme iron can exist in a range of oxidation states in vivo, most commonly as Fe(II) or Fe(III), but the ferryl Fe(IV) is also biologically relevant (see Production of Ferryl Heme and Hemoglobin Protein Radicals). Importantly, only Fe(II) (ferrous) heme can bind O_2. The distal histidine (E7) of globin chains typically stabilizes bound O_2, but under certain circumstances can also bind the sixth coordinate position of heme iron to form structures termed *hemichromes* or *hemochromes* when the iron is oxidized or reduced, respectively.

Hemoglobin Quaternary Structure

Quaternary structure refers to the packing of protein subunits into a multimeric complex. During Hb assembly, α and β monomers join to form a very high-affinity αβ dimer (association equilibrium constant $[K_A] > 10^{10}\ M^{-1}$) (Fig. 19-4, *A*). Two identical α1β1 and α2β2 dimers interact to form a tetramer, in which the constituent dimers are related by a two-fold rotational (C2) symmetry (see Fig. 19-4, *B*). This interaction between dimers is coupled to O_2 ligand binding, with deoxygenated dimers having a higher affinity for self-association to form tetramers ($K_A \approx 4 \times 10^{10}\ M^{-1}$) than fully oxygenated dimers ($K_A \approx 10^6\ M^{-1}$).[29,30] The major dimer–dimer contacts involve nonidentical chains at the α1β2 and α2β1 interfaces. Changes in the interactions between α1β1 and α2β2 dimers are central to the mechanism of cooperative O_2 binding (see Fig. 19-4, *C*).

Free globin subunits, particularly the apo forms lacking heme, are unstable and toxic as monomers[31] and must be assembled rapidly and efficiently into Hb tetramers during erythropoiesis. The order of globin subunit assembly into mature Hb tetramers is unknown, but probably involves parallel pathways.[32-34] For example, heme may be incorporated into apo α or β globins before or after their assembly into αβ dimers. In mammals, nascent apo or met α globins may be bound and stabilized by the molecular chaperone alpha Hb stabilizing protein (AHSP) during the early steps of Hb assembly in vivo.[33,34,35,36]

Dioxygen Binding

The Oxygen Carrying Capacity of Hemoglobin

The solubility of O_2 in water (≈0.3 mM at 20° C and 1 atm) is insufficient to achieve full tissue oxygenation in most animals. Consequently animals have evolved to use heme or other respiratory pigments to transport O_2. However, O_2 rapidly oxidizes free heme from the Fe(II) to Fe(III) state, which cannot bind O_2 (see Redox Reactions of Hemoglobin). To overcome this potential limitation, globin proteins protect the heme group from oxidation and fine tune ligand binding to allow for reversible O_2 uptake and delivery. Hb carries O_2 from the lungs to peripheral tissue capillaries and CO_2 in the reverse direction. The concentration of Hb tetramers in red blood cells (RBCs) is typically about 5.2 mM (equivalent to ≈21 mM heme), and RBCs typically account for 45% of blood volume, giving a theoretical O_2 concentration of approximately 9 mM. O_2 is 21% by volume in air, which corresponds to roughly 8.75 mM in the gas phase at 1 atm and 20° C (1 mol gas under these conditions occupies 24 L by the ideal gas law). Hence Hb raises the O_2 concentration in blood to the same level as in air.

Residues of the Heme Pocket

Conserved, functionally important residues in the heme pockets of α and β globin are shown in Figure 19-2. The

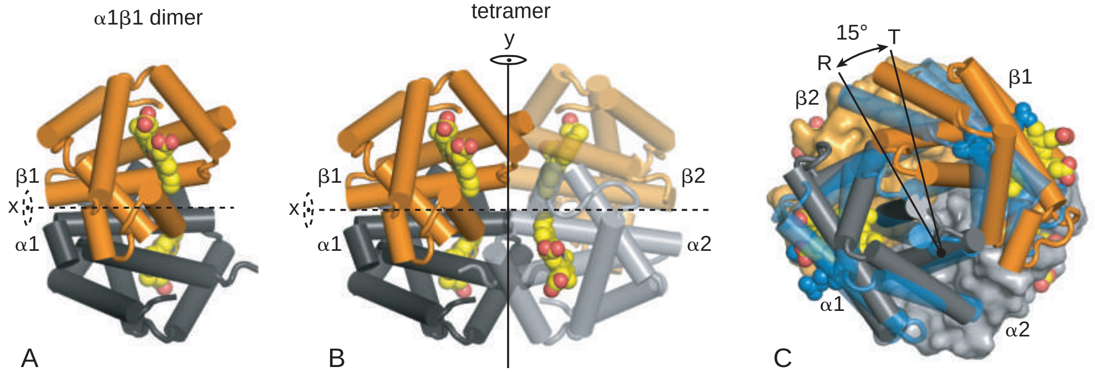

Figure 19-4 Quaternary structure of Hb. **A**, Schematic of the α1β1 dimer with helices shown as solid cylinders and the heme groups in space-fill representation. **B**, The Hb tetramer is comprised of two αβ dimers, related through a twofold rotational (C2 symmetry) axis *(y)*. A pseudo twofold axis *(x)* perpendicular to *y*, relates the positions of the α and β chains in each dimer. **C**, Looking down the pseudo twofold x axis, the van der Waals surface of the α2β2 dimer is shown. The position of the α1β1 dimer in the R (oxy) quaternary state is shown as *gray/orange cylinders* and *yellow hemes*. The position of the same α1β2 dimer in the T (deoxy) quaternary state is shown in *blue*. The α1β1 dimer undergoes a rotation of 15 degrees with respect to α2β2 about an axis that passes through both α chains.

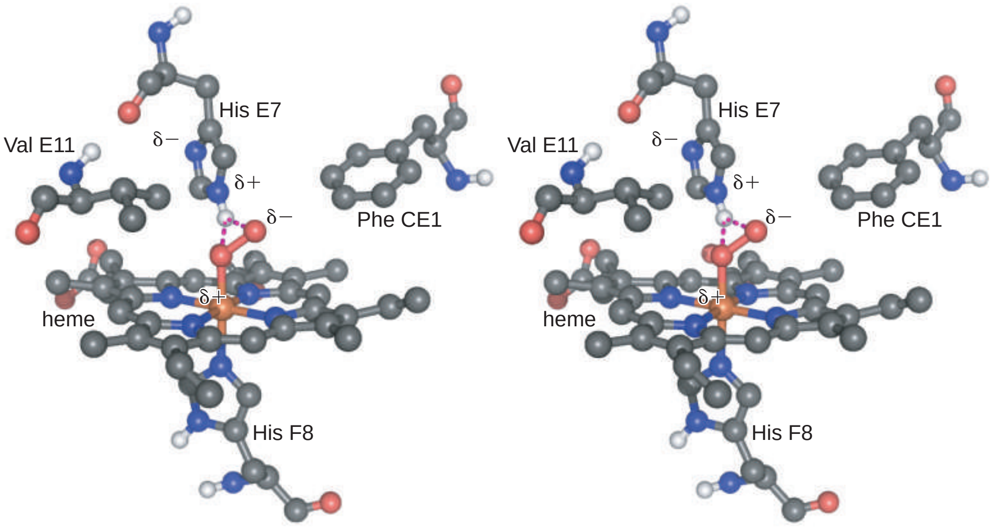

Figure 19-5 Binding of O_2 in the heme pocket. Stereo (cross-eye) diagram of the heme pocket of Hb β subunit. The heme Fe(II) *(orange sphere)* is coordinated by Nε of the proximal His F8. The iron–O_2 complex is polar, with net transfer of negative charge to O_2 *(red spheres)*.[37] The polar Fe–O_2 interaction is stabilized by hydrogen bonding *(magenta)* with the distal His E7. Phe CE1 helps hold the heme in place and orients both bound O_2 and His E7 for more efficient hydrogen bonding. Val E11 contacts the bound O_2 and helps restrict solvent access to the distal pocket.

proximal His-F8 stabilizes an axial iron ligand, which is essential for establishing the octahedral metal coordination geometry that is necessary for O_2 binding. Electrostatic interactions between bound O_2 and the distal His-E7 are of primary importance for ligand selectivity (Fig. 19-5)[37] and inhibiting heme oxidation (autoxidation).[38] In both α and β globin, hydrogen bonding between His-E7 and O_2 has been identified through high resolution (1.25 Å) x-ray crystal structures,[17] nuclear magnetic resonance,[39] electron paramagnetic resonance (EPR),[40] and site-directed mutagenesis.[41] This interaction contributes around 1.9 kcal mol^{-1} to O_2 binding affinity.[41] The importance of this interaction is illustrated by an approximate thousandfold increase in the O_2 dissociation rate from Mb when the distal His is replaced with a nonpolar amino acid.[37,41] A number of nonpolar side chains in the proximal heme pocket make important steric interactions with bound O_2 (see Fig. 19-2, *yellow*). In particular, αPhe CE1/βPhe CD1, which is highly conserved in all globins, stabilizes the heme group and helps orient bound O_2 and His-E7 for efficient hydrogen bonding. βPhe-CD4 (αPhe-CE4) also plays a role in positioning of the distal His side chain to enable O_2 binding (see Fig. 19-2).[42] In the proximal heme pocket, Leu F4 prevents water from entering and disrupting the His F8–iron bond.[26]

The heme pocket of globins is relatively enclosed (see Fig 19-1, *D*), and multiple routes of O_2 entry have proposed, based on binding studies of xenon gas into nonpolar cavities of Mb[43-45] and Hb.[46] X-ray crystallographic and kinetic analyses of Mb[47,48] and Hb[41,49,50] indicate that O_2 enters via a channel caused by outward rotation of the distal His-E7 (see Figs. 19-1, *D*, and 19-2, *cyan*), which allows direct entry into the pocket rather than migration through other cavities in the protein.

In addition to O_2 binding, ferrous Fe(II) Hb also binds carbon monoxide (CO) and nitric oxide (NO) (see Nitric Oxide–Hemoglobin Reactions). Studies with model porphyrin systems show that the Fe–CO bond is intrinsically stronger than the Fe–O_2 bond by a factor of 2×10^4.[37,51] If this ratio of affinities were true in the context of an Hb tetramer, then humans would be rapidly poisoned by endogenously produced CO, which is generated by heme catabolism, neuronal function, and cell signaling in the vasculature. High-level environmental CO exposure can also occur from cigarette smoke and internal combustion engines. Thankfully the relative affinity of CO and O_2 is reduced from 2×10^4 in free porphyrins to about 220 in Hb,[52] largely because of the different electrostatic properties of the Fe–CO and Fe–O_2 complexes.[37] The Fe–O_2 complex is highly polar and makes strong hydrogen bonding interactions with the distal His E7 (see Fig. 19-5). In contrast, the nonpolar Fe–CO complex interacts only weakly with the distal His.

Cooperative Oxygen Binding

Binding of O_2 to Mb can be described by a simple one–binding-site model that yields a hyperbolic curve (Box 19-2 and Fig. 19-6):

$$Y = P_{O2}/(P_{50} + P_{O2})$$

In this equation, Y is the fractional O_2 saturation, P_{O2} is the partial pressure of O_2, and P_{50} is the value of P_{O2} at which 50% of the O_2-binding sites are occupied. For the simple one–binding-site equilibrium, the dissociation constant, K_d, is equal to P_{50}. In contrast, the O_2 equilibrium curve for Hb is sigmoidal (see Fig. 19-6). The initial portion of the curve has a small slope, indicating that fully deoxygenated Hb (deoxy-Hb) has a relatively low affinity for O_2. As O_2 loading proceeds, the slope of the curve steepens, reflecting increasing Hb affinity for O_2. Ultimately, the slope levels off again as Hb approaches O_2 saturation. The shape of this curve indicates that O_2

Box 19-2 **Cooperative Binding of Oxygen to Hemoglobin**

- Cooperative O_2 binding results when the binding of O_2 to one site in Hb increases the O_2 affinity of the remaining sites. Similarly, release of O_2 from one site increases the probability that O_2 will be released from the remaining unbound sites. The overall effect enhances the amount of O_2 that can be bound and released over the narrow range of P_{O2} values that characterize arterial and venous blood (see Fig. 19-6).
- Hb tetramers can bind four O_2 molecules (one per subunit). Binding of several O_2 molecules to deoxy-Hb causes a switch to a high affinity conformation. The high–O_2 affinity Hb quaternary structure is referred to as *relaxed (R),* and the low-affinity Hb structure is referred to as *tense (T).*
- O_2 binding to the heme iron of one Hb subunit alters quaternary structure at the $\alpha1\beta2$ and $\alpha2\beta1$ interfaces of the tetramer, leading to structural changes in the heme pockets of unliganded Hb subunits to enhance their O_2 affinity. As a result, some mutations that affect the $\alpha1\beta2$ and $\alpha2\beta1$ interfaces alter the O_2 equilibrium curve, causing right or left shifts and different amounts of O_2 transport in vivo.

deoxy-Hb, Deoxygenated hemoglobin; *Hb,* hemoglobin; *O_2,* oxygen; *P_{O2},* partial pressure of oxygen.

binding to one or more sites causes an increase in the O_2 affinity of the remaining sites. This property, called *positive cooperativity,* is essential for Hb function.

Conversely, deoxygenation at one or more Hb sites decreases O_2 affinity for the remaining sites, favoring its release in peripheral tissues where O_2 concentration is relatively low. In this way, approximately 1.7 times more O_2 can be delivered to the tissues than would be possible with a hypothetical noncooperative O_2 binding protein with the same intrinsic O_2 affinity. An empirical relationship that described cooperative O_2 binding activity was proposed by A.V. Hill in 1910.[53]

$$Y = (P_{O2})^n / (P_{50})^n + (P_{O2})^n$$

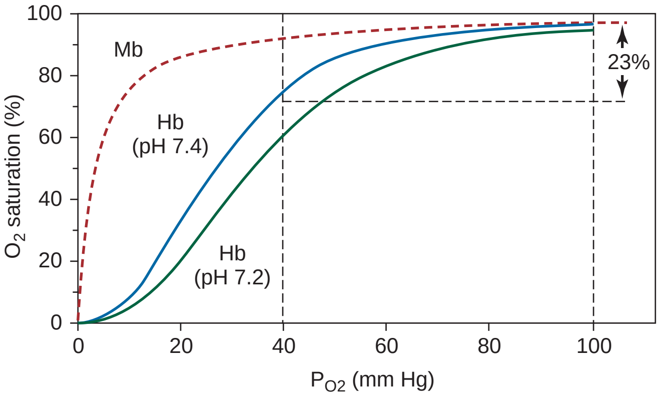

Figure 19-6 O_2 equilibrium curves of sperm whale Mb and Hb in human red blood cells. Myoglobin binds O_2 noncooperatively as a monomer with high affinity. The sigmoidal shape of the O_2 equilibrium curves reflect cooperative O_2 binding. In arterial blood (pH 7.4, 37° C, P_{O2} 100 mm Hg), O_2 saturation is 98%. In mixed venous blood (pH 7.2, 37° C, P_{O2} 40 mm Hg) O_2 saturation is 75%. The HbO_2 saturation difference between arterial and venous blood reflects the extent of O_2 delivery to peripheral tissues. *(From Imai K:* Allosteric effects of haemoglobin, *Cambridge, 1982, Cambridge University Press.)*

The exponent, *n,* termed *Hill coefficient*, measures cooperativity. A value of $n > 1$ represents positive cooperativity. A value of $n = 1$ yields no cooperativity. A value of $n < 1$ results in negative cooperativity. The Hill coefficient for HbA is approximately 2.8. Note that for the cooperative binding reaction, the apparent K_d is equal to $(P_{50})^n$ and is not the ligand concentration at half saturation.

Although the Hill equation reproduces the observed O_2 binding of Hb reasonably well, it implies simultaneous binding of multiple O_2 ligands.[54] G.S. Adair determined that Hb contained four binding sites for O_2[55] and formulated a sequential binding model in which each O_2 binds with progressively higher affinity to each of the four sites.[56] Adair's equation gives an accurate fit to the experimental O_2 equilibrium curve and uses a general and physically plausible binding model. However, the generality of the model means that it does not provide any mechanistic insight into Hb cooperativity. In fact, cooperative binding implies some communication between the heme molecules in each globin chain. Before the structure of Hb (or any protein) was determined, Linus Pauling formulated a model based on a direct chemical interaction between heme groups[57] and showed that O_2 binding characteristics could be reproduced, assuming that subunits of Hb were symmetrically arranged such that O_2 at one heme could influence binding at two adjacent sites.[56] Given the distant spacing between the heme groups, communication must be mediated by the Hb protein matrix, with binding at one site sterically affecting O_2 binding to a heme group at another ("allo-") site on an adjacent subunit.

Allostery and the Perutz–Monod, Wyman, Changeux Model of Hemoglobin Function

The term *allosteric* was first coined in 1961 by Monod and Jacob[58] to described how regulatory ligands could influence the activity of enzymes by binding to distinct sites that did not overlap with the substrate binding site.[59] Allostery, an extremely important concept in biochemistry, has been described as "the second secret of life," second only to the genetic code.[60] The Monod, Wyman, Changeux (MWC) model, developed in the early 1960s,[61] still forms a theoretical basis for understanding cooperative O_2 binding to Hb. The theory itself was influenced by the structural view of Hb provided by Perutz.[59] A key finding from Perutz and colleagues was the elucidation of the human deoxy-Hb structure at 5.5 Å,[62] which provided an opportunity for comparison with the earlier structure of horse oxygenated Hb (HbO_2), also at 5.5 Å.[16] At this resolution no difference in the structures of the individual subunits could be clearly identified. However, there was a clear difference in the quaternary structure. Perutz and colleagues noted that, "the two β chains in human reduced (deoxy-)Hb have moved apart, increasing the distance between their two haem groups 7 Å compared with that in horse oxyhaemoglobin."[62] This quaternary structural rearrangement of Hb in response to O_2 binding is at the heart of the MWC model.

The MWC model is shown in Figure 19-7, *A*. Its basic principle is that quaternary structural changes in Hb regulate the O_2-binding affinity of the subunit chains. The

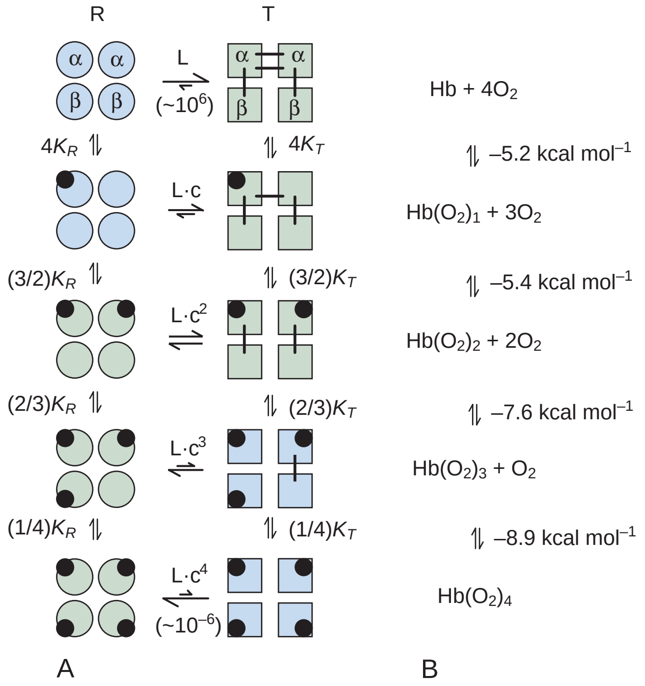

Figure 19-7 Model for cooperative O_2 binding. **A,** A schematic of the MWC-Perutz model[61,465] based on Eaton, et al.[56] The four subunits of the R or T quaternary structure are indicated as *four circles* or *four squares*, respectively. A *solid black sphere* represents an O_2 molecule bound to one subunit. The affinity constant for O_2 binding to any one subunit in the R or T state is K_R or K_T, respectively, hence there is no cooperativity within the R or T quaternary state. With no O_2 bound, the ratio of the T and R state is $L = [T_0]/[R_0] \approx 10^6$. Specific molecular interactions (e.g., salt bridges) between T state subunits (represented by *joining lines*) are broken upon conversion to the R state. Binding of each O_2 molecule weakens these T state quaternary interactions by a factor $c = K_T/K_R \approx 10^{-3}$,[94,95,465] shifting equilibrium towards the R state. The highly populated quaternary states at each oxygenation level (accounting for >90% of Hb molecules) are *green*; the minor quaternary species are *pale blue*.[465] **B,** The free energy change for successive O_2 binding events, obtained by fitting O_2 equilibration data obtained under standard conditions (21.5 °C, pH 7.4, 0.18 M Cl^{-1}) to the four Adair binding constants, after adjustment for dimer-tetramer equilibrium.[69] Note that binding becomes more favorable (*ΔG* more negative) as O_2 saturation increases.

MWC theory describes Hb as a symmetrical oligomer that can adopt two distinct quaternary structures, termed the *tense (T)* and *relaxed (R)* states or conformations. The T and R states are in equilibrium, and in the absence of O_2, the T state is much more stable than the R state (see Fig. 19-7, *A, top row*). The equilibrium between the T and R states of unliganded Hb is defined by the MWC parameter, $L = [T_0]/[R_0]$, where *[T₀]* and *[R₀]* are the molar concentrations of the zero-liganded T and R states. In the T state, all the subunits have a tertiary conformation with low–O_2 affinity (small association equilibrium constant K_T or high P_{50}), whereas in the R state, all subunits have a tertiary conformation with high–O_2 affinity (large association equilibrium constant K_R or low P_{50}). Note that O_2 binding to the individual T (or R) state tetramers does not increase the affinity of the T (or R) state for binding additional O_2 molecules, so there is no cooperativity within the T (or R) quaternary state. However, because O_2 preferentially binds to empty sites in the R quaternary state rather than the T state ($K_R > K_T$), the T→R equilibrium must shift towards R with the addition of O_2, according to the Le Châtelier principle. The basis for cooperativity is that the T→R quaternary switch involves a concerted switch of all subunits from the low–O_2 affinity tertiary structure to the high–O_2 affinity structure (*right-to-left shifts* in Fig. 19-7, *A*). The level of cooperativity is determined by the parameters *L* and *c* = K_T/K_R. The MWC model provides a good fit to experimental equilibrium O_2-binding data, yielding typical parameters of $L \approx 5\times10^6$ and $c \approx 1.5 \times10^{-3}$ and $1/K_T \approx 80$ torr[56,63] for pH 7.4, 0.15 M NaCl, 21.5° C. These parameters are significantly modulated by pH, salt, and organic phosphate concentration (see Heterotropic Effectors of Oxygen Binding to Hemoglobin). The parameter *c* reveals that the quaternary T→R switch corresponds to a 500- to 1000-fold increase in O_2 affinity. The MWC model neglects differences between α and β affinities, but these are likely to differ by less that twofold.[41,64] Many excellent reviews of the MWC model with expanded and refined models are available.[56,65-67]

In order to move from the unliganded T_0 state to the fully O_2-liganded R_4 state, the bonding and nonbonding interactions that stabilize the T_0 relative to R_0 quaternary structures (see *lines joining T-state subunits* in Fig. 19-7, *A*) must be broken using free energy provided by O_2 binding. Consequently the free energy for binding of each successive O_2 becomes more favorable (see Fig. 19-7, *B*). In the unconstrained R state, each binding event would yield −8.35 kcal mol⁻¹.[68,69] The difference between the free energy for binding four O_2 molecules in HbA (−27.1 kcal mol⁻¹) compared with binding in the unconstrained R state (−33.4 kcal mol⁻¹) is called the *cooperative free energy of binding* ($\Delta G_c = +6.3$ kcal mol⁻¹).[68,69] To provide a molecular explanation for how O_2 binding is coupled to changes in tertiary and quaternary structure, Perutz developed his stereochemical model for cooperative O_2 binding,[70] which is described in the following sections.

The High- and Low-Oxygen Affinity Quaternary Structures of Hemoglobin

The stereochemical mechanism proposed by Perutz identifies the T and R states within the MWC model as two discrete quaternary structures that differ in the relative orientation of the α1β1 and α2β2 dimers within the context of the Hb tetramer.[70,71] The T-to-R quaternary switch of the tetramer involves about a 15-degree rotation of the α1β1 dimer relative to α2β2 (see Fig. 19-4, C).[71] The rotation occurs around an axis perpendicular to the C2 symmetry axis and passes through both α subunits. The β chains experience greater relative movement, moving closer together in the R state (as originally observed by Perutz).[62] At the same time, the central cavity between the four globin chains, particularly the cleft between the β subunits, narrows in the R state and inhibits binding of 2,3-DPG, an important modulator of O_2 affinity (see *2,3-Diphosphoglycerate*).

Interactions between α1β1 and α2β2 dimers (i.e., α1β2 interactions) are weaker in the R (oxy) state compared with the T (deoxy) state, which accounts for the observation that R-state tetramers dissociate into $\alpha 1\beta 1$ dimers at low protein concentrations, whereas T state Hb remains a tetramer and emphasizes the role of $\alpha 1\beta 2$ interactions in cooperative O_2 binding. In contrast there is little or no change in the $\alpha 1\beta 1$- (or $\alpha 2\beta 2$-) dimer interface between the T and R quaternary states. Consequently residues at these interfaces do not contribute significantly to allostery. Accordingly, free α and β monomers[72] and $\alpha 1\beta 1$ dimers[73] bind O_2 noncooperatively with a high affinity similar to that of R-state tetramers. Conversely, when crystallized[74,75,76] or embedded in a silica gel,[77] T-state Hb cannot undergo a quaternary T→R transition and binds O_2 noncooperatively at low affinity. These latter findings demonstrate that interactions at the $\alpha 1\beta 2$ interface reduce O_2 affinity in the T state and to a first approximation account for the tetramer's cooperativity.

In tetrameric Hb, the α_1 chain contacts both the α_2 and β_2 chains. Each of these interfaces plays a role in the allosteric mechanism. Interactions between nonidentical chains ($\alpha 1\beta 2$ and $\alpha 2\beta 1$ contacts) account for the majority of the buried surface area. A more restricted set of $\alpha 1\alpha 2$ contacts are present in the T and R states. The $\beta 1\beta 2$ interface is present in the R state but is lost as the β chains move apart in the T structure.

Shown in Figure 19-8, *A*, is the $\alpha 1\beta 1$ dimer with the contact face for the $\alpha 2\beta 2$ dimer facing up out of the page (the $\alpha 2\beta 2$ dimer has been removed to reveal the contact surface). The $\alpha 1\beta 2$ and $\alpha 2\beta 1$ interfaces include the C helix and the FG corner (residues between the F and the G α helices) in each chain. These elements are colored *blue* and *magenta* in the α_1 and β_1 subunits shown in Figure 19-8. The C helix from each Hb chain contacts the FG corner from the nonidentical chain across the $\alpha 1\beta 2$ (or $\alpha 2\beta 1$) interface. This interaction creates four pairs of contacts, as shown in Figure 19-8, *B*. In this panel, the C and FG segments of the α_2 and β_2 chains are shown as "bent tubes" overlaying the $\alpha 1\beta 1$ dimer, with the rest of the chain omitted to allow the interface to be seen. Notably, the behavior of the C helix in α and β chains is different throughout the T→R quaternary change and is indicated by their different coloring in Figure 19-8. Specifically, the molecular contacts between the C helices of the β chains (βC) and the FG corners of the α chains (αFG) change very little during the T→R quaternary transition (see Fig. 19-8, *B*, *dark* blue). Therefore the βC–αFG contacts are known as the *pivot* (or *joint*) contacts. In contrast, the αC helix moves relative to βFG corner, experiencing a translation of approximately 6 Å in the direction of the helix axis, equivalent to approximately one helical turn (5.4 Å) relative to the βFG corner (see Fig. 19-8, *B*, *magenta*). The two alternative positions of the βFG loop relative to the αC helix are dictated by different side-chain packing interactions. Hence βAsp-99 in the βFG corner fits between the side chains of αThr-41 and αTyr-42 from the αC helix in the T state (Fig. 19-9, *B*). In the R state, βFG is shifted such that the side chain of βHis-97 fits between αThr-38 and αThr-41 in the αC helix (see Fig. 19-9, *A*). These two alternative positions of the αC–βFG contact have led to this contact being described as the "switch" region of the $\alpha 1\beta 2$ interface. It is thought that steric hindrance makes intermediates between these two positions unstable,[71] giving rise to the two-state TR quaternary switch. The $\alpha 1\beta 2$ interface is also characterized by different inter–subunit-hydrogen bonding patterns in the T and R states (Fig. 19-10). The intricate nature of the switch region allows mutations at these residues to significantly perturb the stability of the T state (*L* value in the MWC model) and therefore Hb function, sometimes with clinical consequences (see the second part of this chapter).

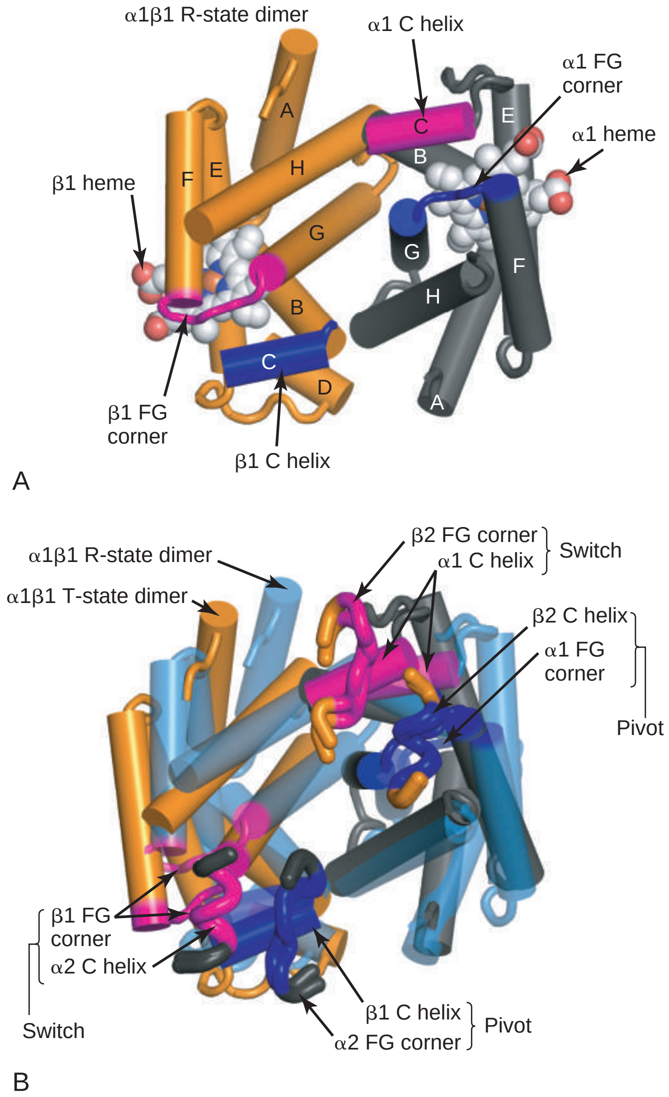

Figure 19-8 The $\alpha 1\beta 2$ interface: switch and pivot interactions. **A**, The $\alpha 1\beta 1$ dimer from R-state HbA (Protein Data Bank [PDB] 2DN2) is shown with the $\alpha 1\beta 2$ dimer removed to reveal the interdimer interface, looking down the pseudo twofold axis, *x* (see Fig.19-4, *A*). Major contacts between the dimers are mediated by the C helices and FG loops (*blue* and *magenta*). **B**, The $\alpha 1\beta 1$ dimer from T-state HbA (PDB 2DN1) is shown *(orange, dark gray)*, superposed with the R-state structure from **A** *(light blue transparency)*. The positions of the $\alpha 2\beta 2$ dimers has been fixed to reveal the rotation of $\alpha 1\beta 1$ between T and R structures. Only the C and FG segments of the $\alpha 2\beta 2$ chains are shown (flexible "tubes"). Contacts between αFG and βC *(blue)* experience little change upon conversion from T to R ("pivot" contacts). In contrast, the αC helix moves relative to βFG loop (*magenta*; "switch" contacts).

Figure 19-9 The α1β2 switch contact. Side chains of the βFG loop *(orange)* pack into grooves that are defined by side chains on the αC helix *(gray)*. To switch from the R state (PDB 2DN1) to the T state (PDB 2DN2), the βFG loop must move between two "valleys" that are separated by a "hill," which is αThr 41.

Although the switch region helps define distinct T and R structures, a range of R quaternary structures have been observed. For example, the C2 symmetry axis in liganded Hb that is crystallized under low-salt conditions at pH 5.8 is distinct from the T or R state structures determined at a neutral or high pH.[78,79] This additional quaternary structure, R2 HbO_2 has been proposed to be either an intermediate in the T→R transition[78] or a true end-point for fully oxy-Hb.[80,81] The current understanding is that in the thermodynamic R state (fully oxy-Hb) proposed by the MWC model, Hb exists in a range of conformations, rather than as a single rigid structure. Crystal structures of the R, R2, and other quaternary variations[82] provide information about the range of structures that are energetically accessible to HbO_2. In support of this interpretation, recent measurements of O_2 binding to crystallized R- and R2-state Hb reveal that these are thermodynamically equivalent states,[83] and a nuclear magnetic resonance (NMR) study of Hb in solution suggests that the average structure of liganded Hb lies approximately halfway between the crystallographic R- and R2-states.[84] Despite considerable variation in the C2 symmetry axis between different R-state crystal structures, a set of common interactions between residues at the α1β2, α1α2, and β1β2 interfaces can be used as structural markers that identify the thermodynamic R state.[17]

Altered Oxygen Binding at the Heme Site in the T and R States

In the unliganded state, pentacoordinate heme iron (Fe[II]) makes four bonds to pyrrole nitrogens and one axial bond with proximal His F8 (α87 or β92). A water molecule sits in the distal pocket of the α chain but does not coordinate the heme iron. The distal pocket of β chains appears empty, or there is no discrete position for a water molecule. The heme site in T-state deoxy-Hb has a high-spin Fe(II) electronic configuration, and the iron is displaced 0.4 to 0.6 Å out of the plane of the four pyrrole nitrogen atoms in the direction of the proximal His F8 ligand. Studies on model porphyrins indicate that an out-of-plane iron is the preferred structure for high-spin Fe(II) porphyrin and hence the iron site in T-state deoxy-Hb is unstrained. Importantly, O_2 binding requires a change in electronic configuration to a low-spin, hexacoordinate, in-plane iron. This configuration is seen in R-state HbO_2 where the heme iron is only 0.09 and 0.06 Å out of the porphyrin plane in α and β chains, respectively.[17]

Figure 19-10 Detail of the α1β2 interface in the deoxy T state (PDB 2DN2) and oxy R state (PDB 2DN1). Hydrogen bonding networks in each state employ nonoverlapping sets of side chains (intrachain hydrogen bonds, *black*; interchain hydrogen bonds, *magenta*). Hb variants at these residue positions can alter the T→R equilibrium. Thus β99 (G1) Asp→Asn (Hb Kempsey) compromises electrostatic interactions only in the T state, thereby favoring the R state and resulting in high–O_2 affinity. Conversely, β102 (G4) Asn→Thr (Hb Kansas) disrupts the R state leading to low–O_2 affinity.

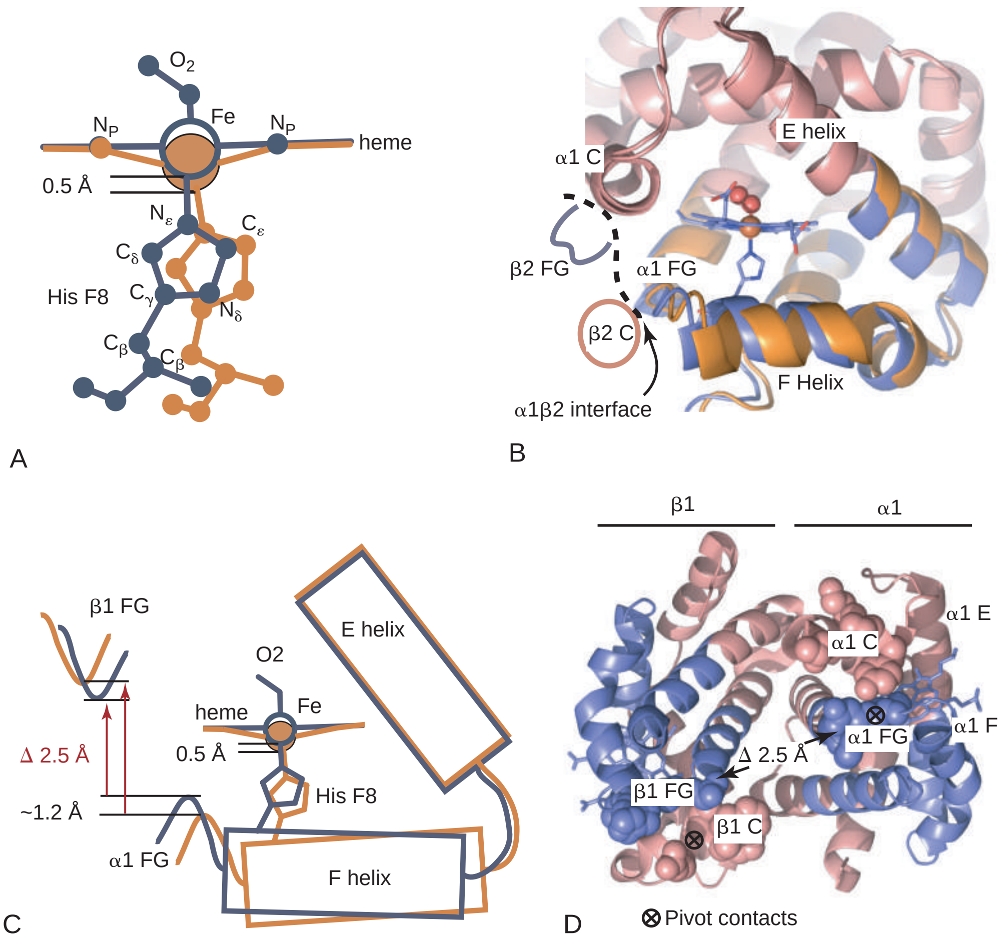

Figure 19-11 O_2 binding is coupled to tertiary structural changes in globin chains. **A,** Schematic of the heme and proximal His F8 in T-state deoxy-Hb *(orange)* and R-state oxy-Hb *(blue-gray)*, looking along the plane of the porphyrin. The central iron atom (*orange sphere* in deoxy Hb) moves about 0.5 Å into the plane of the porphyrin ring upon O_2 ligation. Steric repulsion between His F8 Cε and heme pyrrole nitrogens (N_P) introduces an energetic penalty against iron moving into the heme plane in the T state. Atoms are not drawn to scale. **B,** The most significant tertiary structure changes between α-globin chains from T- and R-state Hb occur at the F helix and EF loop, with smaller changes in parts of the E, G, and H helices (T state, *orange*; R state, *blue*). Other regions are essentially unchanged *(salmon)*. **C,** Movements of the F helix and FG corner are linked to movement of the heme iron, coupled through the His F8 side chain. Combined motions of the α and β chains from a single α1β1 dimer results in the FG loops moving approximately 2.5 Å closer together (T state, *orange*; R state, *blue-gray*). **D,** The α1β1 dimer is the base structural unit of hemoglobin. The stable portion of the dimer, including the α1β1 interface *(pink)*, supports the allosteric core of each chain *(blue)*, which includes the heme group *(sticks)*, EF corner, F helix, and FG corner. Changes in the allosteric core, including movement of the FG corners, couple O_2 binding to quaternary structural changes.

Hence the iron site in R-state HbO_2 is also unstrained. However, accommodating the O_2-liganded heme in the T-quaternary structure introduces strain into the Hb structure because movement of iron into the porphyrin plane requires upward movement of the F-helix away from the α1β2 interface and consequently reduces the free energy of O_2 binding.[75,85-89] Thus in effect, the low–O_2 affinity of the T state can be explained, because the O_2-liganded heme is a poor fit in the T-state structure. In the R-state oxy-Hb, the His F8 imidazole ring is positioned over the heme such that the Fe–Nε bond is normal to the plane of the porphyrin (Fig. 19-11, *A*, *blue*). This geometry is important to minimize steric repulsion between the imidazole and porphyrin rings when iron is in the porphyrin plane.[88] However, in the T-state structure, the His F8 imidazole is rotated relative to heme plane (see Fig. 19-11, *A*, *orange*). In this position there is a greater energetic cost for moving iron into the heme plane because of steric repulsion between Cε of His F8 and the pyrrole nitrogens of the porphyrin.[88]

Determining how strain, introduced into T-state Hb by O_2 binding, is distributed across the tertiary and quaternary T-state structure is the subject of ongoing research. In Perutz's stereochemical model, the strain energy is at least partly compensated (or "stored") by salt bridges present only in the quaternary T state, as described in the following sections.

Quaternary Interactions Contribute to Cooperativity

Salt bridges are electrostatic interactions between oppositely charged groups. These can involve the side chains of basic amino acid residues (Arg or Lys), acidic residues (Glu and Asp), N-terminal amino groups, or C-terminal carboxyl groups of polypeptide chains. Perutz identified eight specific salt bridges present in the T state (but not the R state) that stabilize the low-affinity quaternary conformation.[70] More recent, higher-resolution crystal structures of T-state (deoxy-Hb) and R-state (oxy- and carbonmonoxy-Hb) Hb suggest minor modifications of this set of interactions (Table 19-2).[17,90] In the R state, these interactions are largely replaced by weaker hydrogen bonding interactions between polar residues or to water molecules. For example, the C-terminal residues αArg 141 (HC3) and βHis 146 (HC3) participate in T-state–specific salt bridges (Fig. 19-12).[89-91] Removing both αArg 141 and βHis 146 with carboxypeptidase B increases O_2 affinity and reduces cooperativity for the resultant modified Hb molecule.[91] Similar conclusions were obtained using T-state Hb trapped in gels. Removal of αArg 141 alone caused a 15-fold increase in O_2 affinity of the T state,[92] compared with a threefold increase for the β146 His→Leu mutation.[93]

*Rows containing _asterisks_ indicate salt bridges. No _asterisk_ indicates hydrogen bonding interactions.

Beginning with Szabo and Karplus,[94] several groups created mathematical models suggesting that T-state–specific salt bridges could account for the free energy of cooperativity. Consistent with experimental evidence, some models suggested that ligand binding in the T state strains but does not break the salt bridges.[85,86,95] Importantly, it seems that the lower O_2 binding affinity of T-state Hb is the result of effects from salt bridges and other interactions at the α1β2 interface, which transmits ligand-induced strain in the allosteric core (heme, proximal His, F helix and FG corner).[85,86,95] Crystallized T-state deoxyHb can be oxygenated without switching to the R structure. This procedure has revealed changes in the stereochemistry of the heme, shifts in the FG corners towards the R-state quaternary structure, and lengthening (i.e., weakening) of the T-state–specific salt bridges.[75,87] For example, the C-terminal salt bridge between β_1 His 146 (HC3) and α_2 Lys 40 (C5) (see Fig. 19-12) is lengthened by 0.9 Å in the oxy T state compared to the deoxy T state.[87] However, more recent computational approaches conclude that the free energy of cooperativity is also stored across many other molecular interactions.[88]

Hydrogen bonds at the α1β2 interface may also be strained when the T state is liganded.[88,96-98] For example, Hb variants with nonconservative switch-region substitutions at βAsp 99[99] or αTyr 42[100,101] show increased O_2 affinity and reduced cooperativity (see Fig. 19-10 and discussion of Hb Kempsey in High–Oxygen affinity Hemoglobin Variants). In contrast, conservative substitutions of Tyr or Asp gave less marked effects.[98-100] Similarly, at the α1β2 hinge region, the side chain of βTrp37 makes an inter-subunit hydrogen bond in the T state that stabilizes the α1β2 interface in the T relative to the R state,[98,102,103] and mutations of βTrp 37 decrease cooperativity.[97,104]

Coupling of Oxygen Binding to Structural Changes in Hemoglobin

Superposition of the α1β1 dimers from T- and R-state Hb reveals a set of residues that have invariant tertiary structure. A group of 74 residues are used as a reference frame to describe structural changes in the α and β chains, as well as the α1β1 and α2β2 dimers, during T→R shifts.[105] These include α-chain residues 23 through 42 (helices B and C), α 57 through 63 (helix E), α 101 through 111 (helix G), and α 118 through 125 (helix H); and β-chain residues β 51 through 57 (helix D), β 110 through 116 (helix G), and β 119 through 132 (helix H).[17] These reference-frame residues predominantly map to the α1β1 interface, reinforcing the concepts that relative orientation of the α1β1 and α2β2 dimers represents the major quaternary rearrangement associated with cooperative O_2 binding.

The concerted changes in iron coordination and globin tertiary structure are shown diagrammatically in Figure 19-11. During the T-to-R switch, helix F moves closer to the center of the globin, the gap between helices E and F narrows, and the heme iron moves toward the porphyrin ring (see Fig. 19-11, *A*-C). Figure 19-12 Electrostatic interactions at the HbA dimer–dimer interfaces. α1β1 *(light gray, gold)* and α2β2 *(dark gray, orange)* dimers make different sets of interactions in the T *(left)* and R *(right)* quaternary structures. These interactions are summarized in Table 19-2 and depicted in the lower panels of this figure. Note that the central cavity of the Hb tetramer widens in the T state *(top left)* allowing 2,3-DPG to bind at the β1β2 interface *(bottom panel)*.

19-11) the α heme group moves about 0.5 Å towards the back of the heme pocket, and the β heme undergoes a larger translation of 1.5 Å and a 9-degree rotation. Motion of the heme iron in and out of the porphyrin plane upon O_2 binding and/or dissociation is transmitted through the proximal His, causing the F helix to pivot. The relatively rigid α-helical structure allows a small movement of the heme iron in or out of the porphyrin (≈0.5 Å) to be amplified, resulting in relatively large motions at the FG corners. The combined tertiary structural changes in the α and β subunits from the same high- affinity (α1β1 or α2β2) dimer bring the αFG and βFG corners approximately 2.5 Å closer together in the R state (see Fig. 19-11, *D*, *blue*). In contrast, the relative positions of the αC and βC helices are little changed (see Fig. 19-11, *D*, *pink*). The net result of contracting the distance between the FG corners, while keeping the distance between the C helices fixed, is that some of the C-to-FG contacts across the α1β2 interface must altered. As described previously, the α_1C-to-β_2FG contacts break and reform (switch), whereas the α_1FG-to-β_2C contacts pivot, resulting in the 15-degree rotation of α1β1 relative to α2β2 (see Fig. 19-4, C). Although the αC helix (hinge region) does not undergo substantial conformation changes, it is believed to store significant strain upon T-state oxygenation.[86,88,97,102,106]

Several lines of evidence confirm that the bond between iron and the proximal His-F8 plays key roles in transmitting the effect of O_2 binding to the F helix and in promoting structural rearrangements at the tertiary and quaternary level. For example, when deoxy-Hb was crystallized in the T-quaternary state and the crystals were oxidized and soaked with sodium cyanide (CN), the binding of the strong CN ligand to the T-state α chains forced the iron-His–F8 bond to rupture, indicating that introducing ligands into the T-state structure places the iron-His–F8 bond under strain.[107] In another experiment, Ho, Barrick, and colleagues specifically ablated the iron-His–F8 bond using an F8 His-to-Gly mutation and introduced free imidazole, which bound into the proximal heme pocket and coordinated the heme iron. They found that this complex exhibited increased O_2 affinity and reduced cooperativity.[108] This experiment suggested that the proximal heme ligand in wild-type Hb transmits approximately two-thirds of the cooperative free energy of O_2 binding. Steric interactions between the pyrrole rings and heme pocket residues are also involved.[88]

Changes in Tertiary Structure Precede Quaternary Switching

Gibson, Eaton, and their colleagues employed time-resolved spectroscopy to study internal ligand movement and conformational events that occur after laser photolysis of the Fe–CO bond but before bimolecular rebinding of the ligand from solvent.[109] This approach has shown that tertiary structural changes after ligand binding or dissociation occur within a much shorter time frame (hundreds of nanoseconds [ns] to 1-2 microseconds [μs])[110-112] compared with quaternary structural changes (on the order of milliseconds [ms]).[109,112] Computational methods indicate that fast tertiary T→R structural transitions precede slow quaternary switching[85,86] and that tertiary structural changes induced by oxygen binding to multiple subunits increases the probability that Hb will make the T→R switch.[65] These studies show that the "concerted" quaternary switch, integral to the MWC model, is more accurately viewed as a coupling between rapid tertiary and slow quaternary events. Efforts to develop quantitative biophysical models to fully explain the coupling of tertiary and quaternary structural changes to ligand binding, incorporating all equilibrium O_2 binding and kinetic data, are ongoing.[66,67,113-115]

Box 19-3 Allosteric Regulators of Hemoglobin

- Allosteric regulation refers to changes in the structure and activity of a protein that results from binding of regulatory substances outside of the protein's active site.
- Allosteric regulators of Hb modulate O_2 binding by affecting the T-to-R transition.
- Cooperative O_2 binding is a form of allosteric regulation.
- Other allosteric regulators of Hb include H^+, Cl^-, and 2,3-DPG, which bind outside of the heme pocket to alter Hb O_2 affinity.
- CO_2 produced in peripheral tissues generates H^+, which binds Hb to reduce its O_2 affinity, facilitating tissue oxygenation. This is the alkaline Bohr effect.
- 2,3-DPG, a by-product of glycolysis, binds Hb to reduce its O_2 affinity. Hypoxia stimulates 2,3-DPG production to enhance O_2 delivery to tissues.
- Fetal Hb ($\alpha_2\gamma_2$) exhibits low affinity for 2,3-DPG, which facilitates transfer of O_2 from mother to fetus.

Heterotropic Effectors of Oxygen Binding to Hemoglobin

In addition to O_2, other small molecules and ions known as *heterotropic allosteric effectors* bind with different affinities to T- and R-state Hb and as a result impact cooperative O_2 binding (Box 19-3). The physiologically important species are CO_2, hydrogen cation (H^+), Cl^- and 2,3-DPG. In general, these molecules bind more tightly to the T state, thereby reducing the O_2 binding affinity of Hb. This binding causes a "right shift" in the O_2 saturation curve (Fig. 19-13). Heterotropic effectors have their most significant effect at low P_{O2} values, because they augment O_2 release in the tissues. In the lungs, at relatively high P_{O2} (≈95 mm Hg), the slightly decreased O_2 affinity caused by allosteric effectors has little effect on O_2 uptake.

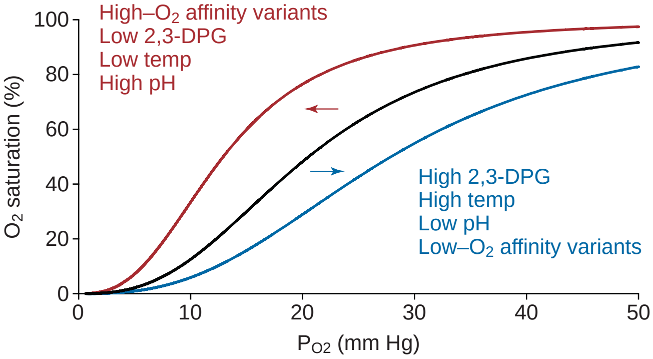

Figure 19-13 Heterotropic effectors alter the Hb-O_2 equilibrium curve. The O_2 equilibrium curve for HbA in cells *(black line)* was simulated using P_{50} = 20 mm Hg and n_{Hill} = 2.7. High pH (low H^+), low 2,3-DPG, low temperature, and high–O_2 affinity Hb variants all cause a "left shift" in the HbO_2 saturation curve (*red line*; simulated with P_{50} = 13 mm Hg, n_{Hill} = 2.7). Low pH, high 2,3-DPG, high temperature, and low–O_2 affinity Hb variants cause a "right shift" (*blue line*; simulated with P_{50} = 28 mm Hg, n_{Hill} = 2.7). All curves are sigmoidal due to the enhanced affinity of Hb for O_2 upon binding successive O_2 molecules (see Box 19-2). *(Modified from Thom CS, Dickson CF, Gell DA, Weiss MJ: Hemoglobin variants: biochemical properties and clinical correlates.* Cold Spring Harb Perspect Med *3:a011858, 2013.)*

Carbon Dioxide Transport and the Bohr Effect

In 1904 the physiologist Christian Bohr showed that CO_2 reduced the O_2 affinity of Hb.[56] Inside RBCs, carbonic anhydrase converts dissolved CO_2 to carbonic acid, which dissociates to bicarbonate and H^+ (i.e., $CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons HCO_3^- + H^+$). Upon conversion from the R to the T state, ionizable chemical groups within Hb bind H^+ ion. Hence increasing [H^+] or decreasing pH shifts equilibrium in favor of the low-affinity T state. The decreased O_2 affinity as pH changes from about 7.4 in the lungs to 7.2 or less in tissue capillary beds is known as the *alkaline* (or *physiological*) *Bohr effect.* Below pH 6.0, the affinity for O_2 increases again. This is called the *acid Bohr effect,* which does not occur in vivo. The physiologic importance of the Bohr effect is that increased pCO_2 (acidification) occurs at sites of high metabolic activity, promoting O_2 release from Hb where it is most required. For example, pCO_2 rises from approximately 35 torr in lung alveoli to about 50 torr in exercising muscles, causing the pH of blood to fall from about 7.4 to 7.2 or lower. This translates into a right-shifted O_2 saturation curve (see Fig. 19-13) with a 25% increase in the P_{50} for O_2 by the alkaline Bohr effect ($\partial \log P_{50}/\partial$ pH = –0.5 in 0.1 M Cl^-, pH 7.4).[71]

Hb facilitates the transport and disposal of CO_2 in several ways. As O_2 is released in actively respiring tissue capillaries, T-state Hb takes up H^+, which promotes conversion of more CO_2 to bicarbonate via deprotonation of carbonic acid in red cells, thereby increasing the CO_2 carrying capacity of blood. Approximately 70% to 80% of CO_2 transport occurs as bicarbonate. In the lungs, the formation of R-state Hb releases bound H^+, converting bicarbonate back to carbonic acid and CO_2, which exchanges with air in the alveoli. An additional 15% to 20% of CO_2 is carried as carbamino-Hb, which is formed by reaction of CO_2 with the terminal amine groups of α and β chains (CO_2 + Hb-NH_2 ⇌ Hb-NH-COO^- + H^+).[116-118] Finally, about 7% of CO_2 gas is simply dissolved in the blood.

The Bohr effect is largely attributed to formation of specific salt bridges involving chemical groups that can bind and release H^+ in response to physiological changes in pH. His residues have basic side chains with pKa of about 6.5, meaning that they can adopt different charge states in the physiological pH range, depending on their chemical environment. In the equilibrium His^+-to-His + H^+ reaction, equal amounts of the charged and neutral His side chains are present when pH equals pKa. When pH is greater than pKa, the neutral state predominates, and when pH is less than pKa, the positively charged state predominates. A key point is that local electrostatic interactions have a significant effect on the pKa value. Salt bridges in the T or low-affinity quaternary conformation stabilize the charged His^+ side chain, increasing its pKa. In other words, the affinity of these His side chains for H^+ is higher in the T state compared with the R state (the necessary condition for an allosteric effector). Then these salt bridges are broken during the transition to the R state when O_2 binds, causing a decrease on pKa and loss of the His protons.

The side chain that contributes most significantly to the alkaline Bohr effect is βHis-146 (HC3), which forms a salt bridge with βAsp-94 (FG1) in T-state Hb[119-121] (see Fig. 19-12). Ho and colleagues measured proton dissociation by NMR to determine the pKa of all His side chains in T- and R-state Hb. They found that the pKa of βHis-146 increases from 6.4 in the R state to 7.9 in the T state and accounts for 60% of the Bohr effect (similar to the finding of Kilmartin et al[122]). Meanwhile, the sum of the contributions from all 13 surface histidyl residues in the αβ dimer accounted for 86% of the alkaline Bohr effect in 0.1 M Cl^-, pH 7.4,[121] the remaining effect being the result of other basic groups including the N-terminal amines.[123] A tertiary Bohr effect has also been described (independent of quaternary bonds), which may involve protonation of buried His side chains including βHis-103 and the distal His side chains in the α and β heme pockets.[98,124,125]

Cl^- is another physiologic inhibitor of O_2 binding that plays a role in the Bohr effect. As bicarbonate ions move out of the RBC down a concentration gradient, they exchange for Cl^-, which is imported into the red cell to maintain charge balance. This exchange is called the *Hamburger* or *chloride shift,* and is mediated by the anion exchange protein Band 3 on the erythrocyte plasma membrane. The alkaline Bohr effect is reduced by approximately 50% in the absence of Cl^-.[68] Virtually all of the chloride-independent contribution of the Bohr effect occurs through βHis-146. Multiple basic groups contribute to the chloride-dependent Bohr effect. The pKa of the amino terminal group of αVal-1 (NA1) and a number of His side chains show O_2-linked pKa changes that are dependent on Cl^- concentration.[126,127] Specific Cl^- binding sites may exist, but these have not been reliably identified through crystallographic studies.[128] A more global network of electrostatic interactions of Cl^- with multiple His side chains,[126] the amino termini, and the positively charged central channel[129,130] may ultimately be involved.

2,3-Diphosphoglycerate

2,3-DPG (also known as *2,3-bisphosphoglycerate* or *2,3-BPG*) is produced from 1,3-DPG as a by-product of glycolysis in a reaction called the *Rapoport-Luebering shunt.* The concentration of 2,3-DPG in RBCs is about 5 mM, approximately equimolar with Hb tetramers. 2,3-DPG is an allosteric inhibitor of O_2 binding and increases the P_{50} of HbA to achieve more efficient O_2 delivery.[131,132] 2,3-DPG carries 5 negative charges that interact with cationic groups lining the entrance to the central Hb cavity between the amino termini of the β chains in the 2,3-DPG binding site[133,134] (see Fig. 19-12). The 2.5 Å crystal structure of HbA containing bound 2,3-DPG reveals the major electrostatic interactions to be salt bridges between the βHis-2 and βLys-82 side chains and the carboxyl and phosphate groups of the effector (see Fig. 19-12). βHis-143 also lies in the binding pocket, but this side chain appears to neutral at pH 7 and may not be essential for 2,3-DPG binding.[121,133] In the R-state structure, movement of the β chains closes the central channel and occludes that binding site for 2,3-DPG. Thus 2,3-DPG binding to Hb causes a large shift in equilibrium towards the T state (15- to 30-fold increase in the MWC parameter, $L = [T_0]/[R_0]$, and a significant decrease in K_T, see Allostery and the Perutz–Monod, Wyman, Changeux Model of Hemoglobin Function).[113,135] Kinetic and equilibrium measurements at O_2 binding suggest that up to 50% of the decrease in P_{50} caused by 2,3-DPG is the result of changes in K_T and perhaps even K_R.[136]

2,3-DPG provides a means for physiological regulation of Hb O_2 affinity under conditions of hypoxia that occur at high altitude. Similarly 2,3-DPG synthesis increases in anemia, favoring O_2 dissociation to counter decreased Hb concentration (see Fig. 19-13). In pregnancy 2,3-DPG can be increased by 30%. Fetal Hb (HbF, $\alpha_2\gamma_2$) shows weak binding to 2,3-DPG compared with HbA,[137] which is presumably an adaptation to the P_{O2} gradient between the maternal and fetal tissues. A number of sequence changes in the N- and C-termini of γ globin, compared with β globin, have been investigated with the conclusion that the diminished 2,3-DPG binding is complex and cannot be attributed to single residue changes.[138,139] HbF also shows limited CO_2 binding as carbamates[140] but retains the chloride independent Bohr effect.[141]

Glycolytic enzyme defects affect 2,3-DPG production and therefore HbO_2 dissociation.[142] In general, glycolytic defects affecting enzymes downstream of 2,3-DPG such as pyruvate kinase result in a higher level of 2,3-DPG, causing a right-shifted O_2 dissociation curve with increased O_2 unloading by red cell HbA in peripheral tissues (see Fig. 19-13). Clinically this reduces the erythropoietic drive. In contrast, glycolytic defects upstream of 2,3-DPG such as hexokinase deficiency cause a reduction in 2,3-DPG concentration and lead to increased Hb O_2 affinity and increased erythropoietic drive. The physiologic differences exhibited in anemic glycolysis defective patients with right-shifted (pyruvate kinase deficiency) versus left-shifted (hexokinase deficiency) O_2-saturation curves are described in a classic study from Oski et al.[143] The patient with hexokinase deficiency (left-shifted curve) demonstrated rapidly decreased central venous P_{O2} tension and increased cardiac output in response to exercise. In contrast, the patient with pyruvate kinase deficiency (right-shifted curve) was able to offload more O_2 to tissues, reflected by a more gradually decreased central venous P_{O2} and a relatively slower rise in cardiac output. Thus at the same Hb levels a patient with pyruvate kinase deficiency (increased 2,3-DPG) has greater exercise tolerance than one with hexokinase deficiency, in which 2,3-DPG production is inhibited.

Redox Reactions of Hemoglobin

Physiologically, iron can exist in the II, III, and IV oxidation states. However, only Hb containing Fe(II) heme is capable of reversible binding to molecular O_2. Oxidation of the heme-iron to the III and IV states can trigger a range of reactions that lead to Hb denaturation and the production of reactive oxygen species (ROS) that damage erythroid cells.

Autoxidation

In the presence of O_2, α and β chains can spontaneously oxidize in a process called *autoxidation*, generating Fe(III) methemoglobin (met-Hb) and superoxide.[144-146] The resulting Fe(III) met-Hb is unable to bind to O_2, exhibits ~60-fold decrease in resistance to denaturation,[22] is prone to form toxic insoluble globin precipitates containing dissociated hemin,[147] and contributes to iron redox cycling and the generation of ROS (see Section on Production of ferryl heme and Hb protein radicals). To counter this, erythrocytes contain high levels of superoxide dismutase and catalase that convert superoxide to H_2O and O_2. Erythrocytes also have high levels of the reducing agents ascorbate and glutathione, as well as a soluble form of cytochrome b5 reductase (also known as met-Hb reductase) that converts met-Hb back to the Fe(II) state. Despite these mechanisms, approximately 1% of Hb exists in the non-functional, oxidized Fe(III) state at any time, probably due in part to reactions with NO. The mechanisms of spontaneous Hb autoxidation have been the subject of much investigation. Early studies suggested that an electron might is transferred from Fe(II) to bound O_2, leading to direct dissociation of superoxide anion[144,146]:

$$\text{Hb–Fe(II)–O}_2 \rightarrow \text{Hb–Fe(III)}^+ + \text{O}_2^{\bullet -}$$

The normal Fe(II)–O_2 bond involves partial transfer of electron density from the iron to the O_2, such that the HbO_2 can be described as $\text{Fe(III)}^+\text{–O}_2^{\bullet -}$.[148] This charge transfer is reversed when molecular O_2 dissociates. The activation barrier for dissociation of negatively charged $O_2^{\bullet -}$ from the positively charged iron center makes the barrier to direct superoxide anion dissociation high. An alternative reaction is an outer sphere electron transfer from the Fe(II)–porphyrin to an O_2 molecule that is not coordinated to the iron:

$$\text{Hb–Fe(II)} + \text{O}_2 \rightarrow \text{Hb–Fe(III)}^+ + \text{O}_2^{\bullet -}$$

However, these reactions by themselves do not explain the dependence of autoxidation on O_2 concentration. It can be shown that both reactions cause autoxidation rate to increase up to a maximum asymptotic value with increasing $[O_2]$.[149,150,151] However, a plot of autoxidation rate against O_2 concentration is bell-shaped, with the maximum rate occurring at approximately P_{50} and an asymptotic value at very high O_2 concentrations.[150,151] Work with various globins and model heme compounds suggested that electron transfer can occur by an outer sphere reaction for hexacoordinate Fe(II)-porphyrin that has a solvent molecule or other anionic ligand (L) at the sixth coordination site to facilitate formation of stable ferric iron complex[145,149-151]:

$$\begin{aligned} &\text{Hb–Fe(II)–O}_2 + \text{L} \rightleftharpoons \text{Hb–Fe(II)} + \text{L} + \text{O}_2 \\ &\quad \rightleftharpoons \text{Hb–Fe(II)–L} + \text{O}_2 \rightarrow \text{Hb–Fe(III)}^+\text{–L} + \text{O}_2^{\bullet -} \end{aligned}$$

Under physiologic conditions, this nucleophilic ligand in the previous reaction is probably water. In the Hb α chain[17,125] and Mb,[152] a fully occupied water molecule is hydrogen-bonded to the distal His in the observed deoxygenated crystal structures. These structural studies show that water can enter the deoxy-Hb heme pocket. An ordered water molecule is not observed in the β heme pocket,[17,125] but fluctuations of the protein conformation in solution almost certainly allow some water to enter.[153]

Consistent with this, β chains have been reported to auto-oxidize seven times more slowly than α chains at pH 6.5.[154] The reaction shown accounts for the drop in auto-oxidation rate at high [O_2] (the bell-shaped curve),[149-151] because O_2 competes with solvent, inhibiting formation of the Hb–Fe(II)–L complex. However, this reaction shown immediately before does not explain the strong pH dependence of the auto-oxidation reaction, the increase in rate when the distal histidine is replaced with nonpolar amino acids, or the limiting value at high [O_2]. The latter three phenomena are accounted for by a dissociative mechanism in which H^+ binds to the coordinated O_2 and neutral superoxide dissociates (c.f., same with bound O_2 protonated):

$$\text{Hb–Fe(II)–O}_2 + \text{H}^+ \rightarrow \text{Hb–Fe(II)–OOH}^+ \rightarrow \text{Hb–Fe(III)}^+ + \cdot\text{OOH}$$

The stabilizing effect of the neutral distal histidine is the result of hydrogen-bond donation to the bound O_2, which inhibits its protonation and prevents dissociation of the protonated superoxide radical. Both processes appear to occur during autoxidation of Mbs and Hbs, with the dissociative mechanism (reaction described immediately before) dominating under aerobic conditions and the outer sphere mechanism dominating under hypoxic conditions.[149-151] The dissociative mechanism readily explains the increased autoxidation and resulting ROS produced under conditions of acidosis after hypoxia and tissue damage, which are likely to be clinically significant. Other autoxidation mechanisms have been proposed, including direct displacement of superoxide from HbO_2 by hydroxide ions at high pH[155] or through interactions of the distal histidine with the iron center caused by fluctuations in the protein conformation during denaturation.[156]

Mutations of the distal His E7 to a nonpolar side chain abrogates the electrostatic stabilization of bound O_2 and leads to 100-fold decrease O_2 binding affinity,[37] along with a 100-fold increase in autoxidation rate.[150,157] Mutations of hydrophobic residues that line the heme pocket, such as E11[158] and B10,[159] to larger or smaller side chains tend to have reciprocal effects on O_2 affinity and autoxidation, consistent with similar direct steric interactions with O_2 or ·OOH. Importantly, autoxidation of Hb is also strongly influenced by oligomerization state. Dissociation of Hb into dimers, as occurs by dilution after hemolysis, leads to a sixfold increase in auto-oxidation.[160] Separated α and β chains show even more rapid auto-oxidation,[154] presumably because of loss of structural integrity and increased hydration of the heme pocket. Consequently the presence of free α and β chains in β-thalassemic erythroid cells leads to oxidative damage (see Ineffective Erythropoiesis in Thalassemia).[161,162]

Nitric Oxide–Hemoglobin Reactions

It has been known for well over 150 years that NO is toxic to most animals, can form an ultra-high affinity complex with deoxy-Hb, and rapidly oxidizes HbO_2 to met-Hb[163,164] (Box 19-4). Until the 1980s, most studies of the reaction of NO with Hb involved binding of the ligand to deoxy-Hb under anaerobic conditions.[165] In the absence of O_2, an Hb(Fe[II])–NO complex is formed rapidly, with a bimolecular rate constant that is almost diffusion controlled ($10^8 M^{-1}s^{-1}$),[41,164,166] and has a distinct free radical Fe(II)–NO EPR signal. This EPR signal is often used to detect the synthesis of NO in endothelial cells or in activated macrophages during inflammation.[167,168] However, exposure of the reduced HbNO complex to air leads to oxidation and met-Hb formation with a rate that is equal to that of thermal dissociation of NO, which is on the order of 10^{-4} to 10^{-5} s^{-1} (half-time of 2 to 20 hours).[169,170] In 1981 Doyle and Hoekstra[171] showed that the products of the reaction of HbO_2 with NO are exclusively met-Hb and nitrate, and later Arnold and Bohle[172] showed that the same products are generated when the reduced HbNO complex is exposed to air. A summary of these reactions of Hb with NO is given in Figure 19-14, *A*.

Box 19-4 Nitric Oxide and Hemoglobin

- HbO_2 can rapidly and irreversibly oxidize NO to NO_3^- in a reaction called *dioxygenation*.
- NO produced by nitric oxide synthetase in endothelial cells relaxes arterial smooth muscle, causing vasodilation.
- During massive hemolysis or after infusion of Hb-based artificial blood substitutes, free plasma Hb can cause hypertension by degrading endothelial cell produced NO.

Hb, Hemoglobin; *NO_3^-,* nitrate ion; *NO,* nitric oxide; *O_2,* oxygen.

The kinetics of NO-induced oxidation of HbO_2 were first examined by Eich and colleagues.[173] The observed bimolecular rate constant is very large (≈1×10^8 $M^{-1}s^{-1}$) and almost identical to that for simple NO binding to deoxy-Hb (see Fig. 19-14, *A*). In both cases, the rate-limiting step is ligand entry and capture in the active site, which can be inhibited by placing large aromatic amino acids in the interior portion of the distal pocket.[140] Gardner and colleagues[174] showed that both atoms of the originally bound O_2 are incorporated into nitrate using $^{18}O_2$ labeling experiments. Thus they verified the process as *NO dioxygenation*, a term he coined in 1998 when he discovered that microbial flavohemoglobins carry out this reaction to detoxify NO produced by macrophages during pathogen-induced inflammation.[175] He also showed that these flavohemoglobins are true enzymes with a built-in flavin reductase that resembles the met-Hb reductase of red cells.[176] Thus both the microbial flavohemoglobins and red cell adult Hb can be considered NO dioxygenases that rapidly remove NO by generating a nontoxic nitrate product (upper reactions in Fig. 19-14. *A*).

The mechanism of the NO dioxygenation reaction is shown in Figure 19-14, *B*. As soon as NO is captured in the distal pocket of Hb, it reacts with bound O_2 to form an oxidized peroxynitrite-Fe(III) transition state that immediately isomerizes to an Fe(III)-nitrate complex that is unstable because of the large size of the nitrate anion.[177-179] At neutral pH and 37° C, this transient intermediate is not observed in rapid-mixing experiments, indicating that the nitrate dissociates in less than 1 ms. The speed and efficiency of the NO dioxygenation reaction suggests strongly that Hb evolved to retain this

Figure 19-14 Key reactions of NO with red cell Hb. **A**, NO can react with either ferrous deoxyhemoglobin (HbFe[II], *blue*) to form a reversible nitrosyl–ferrous complex (Hb[FeII]NO) or with oxyhemoglobin, which leads to oxidation of hemoglobin and NO, generating met-Hb (met-HbFe[III]) and nitrate. The bimolecular rate constants for these processes are similar, very large (50-100 $\mu M^{-1}s^{-1}$), and limited by the rate of NO movement into the distal pocket.[178] Even when HbFe(II)NO is formed, the ultimate fate of the NO is nitrate. During autoxidation of nitrosylhemoglobin, NO slowly dissociates from ferrous Hb, O_2 binds to HbFe(II), and the resultant HbFe(II)O_2 then rapidly reacts with the newly liberated NO to generate met-Hb(FeIII) and nitrate.[178] **B**, The mechanism of NO dioxygenation involves capture of NO in the distal pocket and rapid reaction of this radical with bound O_2 to generate a *cis*-peroxynitrite-oxidized iron intermediate that quickly isomerizes to a transient Fe(III)-nitrate complex, which can be seen at high pH.[179] Normally, the Fe(III)–NO_3^- complex quickly dissociates yielding the final products met-Hb(FeIII) and nitrate. Both oxygen atoms of the originally bound O_2 are incorporated into nitrate with 95% fidelity or greater.[174] *FAD,* Flavin adenine dinucleotide.

activity and keep a large empty space in the interior of the distal pocket to both capture ligands efficiently and allow formation of the peroxynitrite-Fe transition state.

The physiologic relevance of the NO scavenging reactions shown in Figure 19-14, *A*, is clear. The presence of free Hb in plasma, caused either by hemolytic disease or infusion of acellular simple tetrameric Hb-based O_2 carriers, leads to a rapid increase in blood pressure by attenuating the vasodilatory effects of NO synthesized by endothelial cells. Using a library of recombinant Hbs, Olson and colleagues[178] showed that there is a linear correlation between the increase in mean arterial blood pressure in animal transfusion models and the bimolecular rate of NO dioxygenation measured in vitro. These results explain in part the toxicity of plasma Hb, which can move up to and into the vessel walls, scavenge NO, and inhibit vasodilation of the surrounding smooth muscle. In contrast, NO dioxygenation in red cells has an important protective effect. NO is a potent inhibitor of cytochrome c oxidase and can inhibit mitochondrial respiration at nanomolar concentrations by binding to either the reduced or oxidized form of the enzyme.[180] Similarly if NO just displaced bound O_2 it would form a long-lived, high affinity HbFe(II)–NO complex, which would greatly reduce the O_2 carrying capacity of blood.

These toxic effects are prevented by the efficient removal of elevated levels of NO in the blood stream by the NO dioxygenase activity of intracellular Hb. Gladwin and coworkers[181] have unambiguously demonstrated this activity in humans. When six volunteers breathed in 80 ppm NO gas, their levels of met-Hb and nitrate rose together in a one-to-one fashion up to approximately 80 μM after 1 hour. There was little increase in Hb(Fe[II])NO, S-nitrosylhemoglobin, or nitrite, which were all at levels of 2 μM or less. NO dioxygenation by Mb plays a similar role in striated muscle cells by preventing inhibition of respiration during exposure to high levels of NO caused by inflammation or high induction of endothelial nitric oxide synthase (eNOS) for vasodilation.[182,183]

Over the past 15 years, numerous groups have been studying the reactions of nitrite with Hb, both in vivo and in vitro.[184-187] Depending on the presence or absence of molecular O_2, the products of these reactions can range from S-nitrosylhemoglobin with an NO group covalently attached to the thiol side chain of βCys 93 or NO coordinated to a reduced-heme iron atom.[188,189] All of these processes are several thousand times slower than any of the direct NO reactions with HbO_2 and deoxy-Hb shown in Figure 19-14, *A*. S-nitrosylation does not involve free NO, but instead occurs by disproportionation of N_2O_3 into ON^+ and NO_2^-, with the cation reacting rapidly with strong thiol nucleophiles. N_2O_3 is generated either by the reaction of NO with O_2 or protonation and dehydration of two nitrite molecules, and these two reaction pathways are interconnected.[188,189] Thus S-nitrosylation is indicative of either the presence of nitrite or the products of the reaction of NO with molecular O_2, which occur during inflammation.[188,190] Some of these processes are clearly important in vasoregulation; however, it is also important to note that high levels of nitrite (≥100 μM), unlike nitrate, are toxic and cause methemoglobinemia and heme degradation.[191,192] Inside RBCs, where the concentration of Hb subunits is roughly 10^{-2} M, the lifetime of free NO is less than or equal to 1 μs because of the high bimolecular rates of NO dioxygenation by HbO_2 and binding to deoxy-Hb, both of which lead to met-Hb and nitrate. Thus the physiology of NO and intracellular Hb is dominated by the reactions in Figure 19-14, *A*.

Interestingly, Isakson and coworkers recently reported that endothelial cells of resistance arterioles express free α globin, which degrades NO to promote vascular contractility.[193] Suppression of endothelial α globin expression by short hairpin ribonucleic acids (shRNAs) enhanced NO accumulation and reduced contractility in isolated blood vessels. How endothelial α globin regulates blood pressure and local tissue blood flow in vivo remains an open question.

Production of Ferryl Heme and Hemoglobin Protein Radicals

The superoxide anions generated from Hb autoxidation undergo rapid enzymatic and nonenzymatic conversion to hydrogen peroxide (H_2O_2) and O_2. H_2O_2 is a key mediator of oxidative stress that can react with either reduced or oxidized globins to produce highly reactive oxoferryl (HbFe[IV] = O) or oxoferryl radical (Hb•Fe[IV] = O) containing heme groups.[194,195] Simple ferryl iron can subsequently be reduced by second molecule of H_2O_2 to produce Fe(III) and superoxide.

$$\mathrm{HbFe(II)} + \mathrm{H_2O_2} \rightarrow \mathrm{HbFe(IV)} = \mathrm{O} + \mathrm{H_2O}$$

$$\mathrm{HbFe(IV)} = \mathrm{O} + \mathrm{H_2O_2} \rightarrow \mathrm{HbFe(III)} + \mathrm{O_2}^{\bullet -} + \mathrm{H_2O}$$

Superoxide and H_2O_2 can also degrade heme directly, producing fluorescent pyrroles and free iron.[195,196] The reaction of H_2O_2 with Fe(II) is complicated by reduction of ferryl Hb with H_2O_2 to produce superoxide (which in turn can dismute to generate $\frac{1}{2}H_2O_2 + \frac{1}{2}O_2$), comproportionation (the reaction of Fe[II] and Fe[IV] = O species to form two Fe[III] species), and autoreduction involving electron transfer from Hb side chains (producing protein radicals). Fe(III) heme reacts more rapidly than Fe(II) heme with H_2O_2 to produce the oxoferryl radical species.[156,197,198]

$$\mathrm{HbFe(III)} + \mathrm{H_2O_2} \rightarrow \mathrm{Hb{\bullet}Fe(IV)} = \mathrm{O} + \mathrm{H_2O}$$

One electron has to be removed from either the porphyrin ring or the surrounding protein to generate water and the Fe(IV) = O species, and as a result a protein or porphyrin radical is generated. Another H_2O_2 can react with the oxoferryl Hb radical to produce O_2 without heme degradation and to regenerate HbFe(III). These two reaction can consume H_2O_2 with peroxidase or catalase-like activity.[195]

$$\mathrm{Hb{\bullet}Fe(IV)} = \mathrm{O} + \mathrm{H_2O_2} \rightarrow \mathrm{HbFe(III)} + \mathrm{O_2} + \mathrm{H_2O}$$

However, the protein radical and the oxoferryl heme species are highly reactive, and cycling between the Fe(III) and Fe(IV) oxidation states increases the probability of reactions that degrade Hb or other cellular components.[197-199]

Prooxidant Reactions of Hemoglobin

Oxidative reactions of Hb, such as lipid oxidation, have been well studied in vitro. Ferryl heme and Hb radicals can initiate lipid oxidation by abstraction of hydrogen to form a lipid radical. In the presence of O_2, lipid radicals can participate in an autocatalytic cycle that generates further lipid oxidation products.[198] Lipid oxidation products produced at an artery wall can interfere with inflammatory signaling and may contribute to the pathogenesis of atherosclerosis.[199-201]

Evidence for the oxidative reactions of Hb include the detection of globin radicals[202] and degradation products of heme[203] in blood. A greater level of oxidized Hb has been found in venous compared with arterial blood, as detected by EPR.[156] However, in general the involvement of heme proteins in oxidative damage in vivo is hard to establish because of the transient nature of many of the reaction products. Two markers that are considered reliable indicators of oxidative stress in vivo are isoprostanes[204] and cross-linked heme-globin products.[198] Isoprostanes are potent vasoactive compounds that are generated nonenzymatically from lipids found in low-density lipoproteins by radical oxygen species[205] and in vitro can be produced through the reaction of low-density lipoproteins with heme proteins.[206] Heme-Hb cross-links are thought to be exclusively generated by reaction of ferryl heme and a protein-based radical and are therefore stable markers of ferryl heme production from met-Hb and H_2O_2 in vivo.[198]

Detection of these markers has implicated redox reactions of globin proteins under two significant clinical conditions. First, in rhabdomyolysis, muscle breakdown releases Mb, which causes kidney damage from lipid radical formation and the vasoconstrictive action of isoprostanes.[199] Second, after subarachnoid hemorrhage, isoprostanes[199,207] and heme-protein cross-links indicative of ferric–ferryl redox cycling[208] are detected in cerebrospinal fluid. Accumulation of these metabolites may contribute to delayed vasospasm and consequent ischemic brain injury that occurs in about 30% of surviving patients.

In addition to oxidative reactions mediated by heme proteins, the formation of met-Hb promotes heme release because the Fe(III)–His F8 interaction is significantly weaker than the Fe(II)–His F8 bond.[22,209] Folding of Hb chains is stabilized by interactions with heme,[22] and heme loss leads to rapid denaturation of Hb chains. Free iron can be released after peroxide or heme oxygenase breakdown of protoporphyrin IX and participate in the Fenton reaction, which converts H_2O_2 to a hydroxyl anion and a hydroxyl radical. Reduction of Fe(III) by superoxide and subsequent reaction with H_2O_2 generates highly damaging hydroxyl radicals.[198,199,210]

$$\mathrm{Fe(II)} + \mathrm{H_2O_2} + \mathrm{H^+} \rightarrow \mathrm{Fe(III)} + \mathrm{HO\cdot} + \mathrm{H_2O}$$

$$\mathrm{Fe(III)} + \mathrm{H_2O_2} \rightarrow \mathrm{Fe(II)} + \mathrm{HOO\cdot} + \mathrm{H^+}$$

Ineffective Erythropoiesis in Thalassemia

Ineffective erythropoiesis (IE) is a failure to produce mature RBCs because of apoptosis and/or maturation delay of erythroid progenitors, often compounded by premature hemolysis of circulating RBCs. Compensatory increase in erythropoietic drive leads to accumulation of erythroid progenitors in the bone marrow, liver, and spleen. IE is one of the primary pathologies of thalassemia (especially β type) and arises from the toxic effects of excess free αHb.[31] Free globins, particularly α globin, are toxic for several reasons. They have greater susceptibility to denaturation and auto-oxidation,[154] heme loss,[25] and production of ROS.[161,162,211] Levels of ROS are elevated in erythroid cells of β-thalassemic mice.[212-215] These data suggest that ROS production caused by imbalanced Hb synthesis is likely to contribute to cellular damage in thalassemia. However, the role of oxidative stress to IE and hemolytic anemia is still only partly understood. Damage to cell membrane structures through Hb precipitation appears to be a trigger for apoptosis contributing to IE. However, defective cell signaling through erythropoietin (EPO) signaling with consequent increase in proliferation and failure to differentiate also contributes to IE.[216]

ABNORMAL HEMOGLOBINS

Introduction to Hemoglobin Variants

Mutations in globin genes can affect their expression, causing thalassemias (see Chapter 21), or produce structurally abnormal globin proteins (i.e., Hb variants). Many human Hb variants are discovered incidentally and have minimal effects on the Hb molecule or patient. However, naturally occurring Hb mutations can cause biochemical abnormalities with consequent phenotypes ranging from clinically benign to severe. The most common and medically important globin gene mutations include HbS (Chapter 20), HbC (Chapter 20), HbE, and the thalassemias (Chapter 21), most of which are under positive genetic selection because they confer survival advantages against malaria.[1] These abnormalities are therefore most prevalent in populations where malaria is endemic, although global migration is increasing the incidence of such mutations in the United States and Northern Europe. In addition to the common globin gene abnormalities, there are also over 1000 other mutations that are rare individually, but common collectively. Most known Hb mutants are catalogued on the Globin Gene Server[12,13] (http://globin.cse.psu.edu). By convention, these variants are named after the geographic origin of the affected individual. Analyses of Hb variants, which can be considered "experiments of nature,"[217] have generated valuable insights into structure–function relationships within the Hb molecule and the associated clinical consequences. This section provides a conceptual framework for understanding the biology and clinical implications of Hb variants, and it discusses how these variants are ascertained, analyzed, and classified broadly according to their effects on Hb physiology. Selected examples of Hb variants that reinforce basic principles are then described in greater detail.

Identification of Hemoglobin Variants

Unexplained clinical signs and laboratory findings indicative of altered Hb physiology should prompt physicians to consider the possibility of globin gene mutations (Box 19-5). These include pallor and hemolytic anemia (unstable Hbs; see Hemolytic Anemia: Unstable Hemoglobin Variants), ruddy complexion with polycythemia (Hbs with increased O_2 affinity; see Erythrocytosis: High–Oxygen Affinity Hemoglobin Variants), or bluish skin (cyanosis caused by Hbs with decreased O_2 affinity or enhanced oxidation; see Cyanosis: Low–Oxygen Affinity and M-Type Hemoglobin Variants). Routine laboratory testing can also reveal Hb variants incidentally. For example, in many countries, Hb analysis (typically by high-performance liquid chromatography [HPLC]) is performed on all neonates to screen for sickle cell anemia and thalassemia syndromes. This testing can also reveal less common Hb variants by virtue of their abnormal chromatographic mobility. Although such variants may warrant further investigation, they are often clinically

silent. Routine testing in adults can also reveal abnormal Hbs. For example, several Hb variants were discovered because they migrate similarly to HbA_{1c} in chromatographic assays that are used to monitor long-term glycemic control in patients with diabetes (Fig. 19-15).[218-221] Such variants can interfere with diabetic management by artificially elevating or reducing HbA_{1c} measurements. The fact that relatively benign Hb variants can reveal themselves through altered skin color or incidentally through laboratory testing explains why so many have been discovered.

Because Hb variants are so common, they are also likely to be identified via global exome or whole genome sequencing, increasingly common approaches used to investigate many acquired and germline genetic disorders. Incidental findings revealed through such testing, termed the *incidentalome*,[222,223] are likely to include benign Hb variants or reveal carrier status for more clinically significant ones.

Clinical Manifestations of Hemoglobin Variants Reflect Their Physiological Effects

Hb variants are classified according to their effects on the molecule, which influence clinical manifestations (Table 19-3). These classifications include unstable, high–O_2 affinity, low–O_2 affinity and M (met-Hb) type. General clinical issues associated with Hb variants are discussed in this section, and the structural and biochemical effects of such mutations are discussed in Pathophysiology of Hemoglobin Abnormalities.

Hemolytic Anemia: Unstable Hemoglobin Variants

Globin mutations that destabilize Hb tetramers are among three major categories of inherited disorders that cause hereditary hemolytic anemia through erythrocyte-intrinsic abnormalities[224-229] (Table 19-4). Most of these disorders are manifested by neonatal jaundice and/or chronic anemia with reticulocytosis, although lesions in the β-globin gene may present later in the first year of life as adult Hb replaces fetal Hb. With the exception of HbS, unstable variants are a relatively rare cause of hemolytic anemias but must be considered in unexplained cases. The clinical severity ranges from mild to extreme, depending on the nature of the mutation and environmental factors. The most severely affected patients are dependent on RBC transfusion. Fever and/or transient acidosis during intercurrent illness can aggravate hemolysis by increasing denaturation of unstable Hb variants. Patients with unstable Hbs may display dark urine caused by hemoglobinuria and/or bilirubinuria, although these findings do not indicate the degree of hemolysis,[230,231] nor does the absence of pigmenturia rule out this condition.

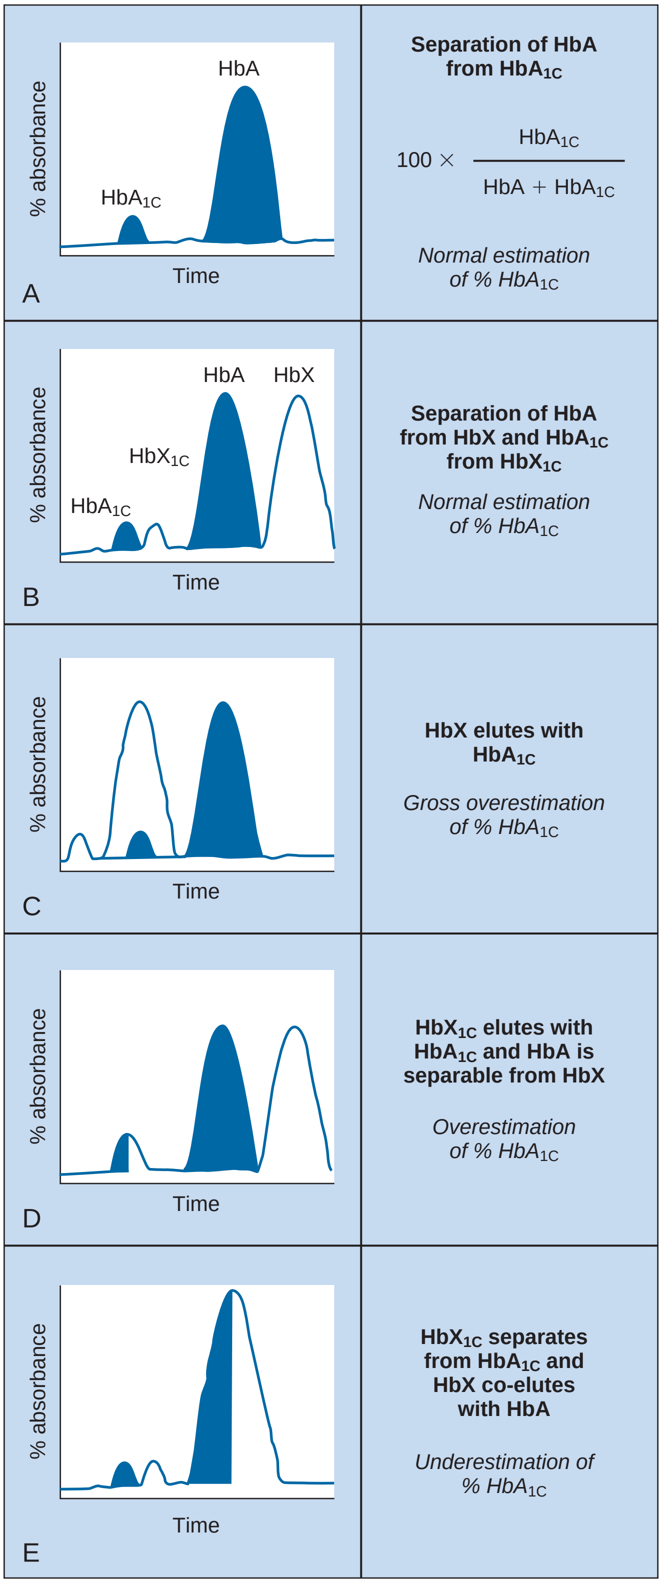

Figure 19-15 Chromatographs showing how Hb variants affect HbA_{1C} quantification. HbA and HbA_{1C} are indicated by *shaded areas*; HbX and HbX_{1C} (variant Hb) are indicated by *unshaded areas*. **A**, Subject with no variant Hb. **B**, HbX and its glycated form (HbX_{1C}) fully separate from HbA and HbA_{1C}, respectively. **C**, HbX comigrates with HbA_{1C}, causing overestimation of the percentage of HbA_{1C}. **D**, HbX_{1C} and HbA_{1C} comigrate, whereas HbA and HbX separate. This result produces a mild, spurious increase in the percentage of HbA_{1C}. **E**, HbX_{1C} and HbA_{1C} separate, while HbA and HbX co-elute. This produces a spurious decrease in the calculated percentage of HbA_{1C} value. *(From Bry L, Chen PC, Sacks DB: Effects of hemoglobin variants and chemically modified derivatives on assays for glycohemoglobin.* Clin Chem *47:153–163, 2001.)*

TABLE 19-3 Classification of Hemoglobin Variants

Hb Variant Class	Signs and Symptoms	Structural Alteration
Unstable	Hemolytic anemia, dominant thalassemia	Destabilized 2°, 3°, or 4° structure Impaired heme–globin interactions
High–O_2 affinity	Erythrocytosis	Stabilized R state Impaired Bohr effect Impaired 2,3-DPG binding site
Low–O_2 affinity	Cyanosis	Stabilized T state
M (Met) Hb	Cyanosis, methemoglobinemia	Altered heme pocket
Multiple effects	Varied	Combinations of the above

2,3-DPG, 2,3-Diphosphoglycerate; *Hb*, hemoglobin; *O_2*, oxygen; *R*, relaxed; *T*, tense.

Other associated signs or symptoms of hemolytic anemia with unstable Hb variants (or other etiologies) include persistent or intermittent jaundice, gall bladder disease, and splenomegaly. In many forms of congenital hemolytic anemia, including those associated with unstable Hb variants, parvovirus B19 infection can cause red-cell aplasia with severe, sometimes life-threatening anemia. In undiagnosed patients, this clinical presentation can be mistaken for disorders of red-cell hypoplasia, such as transient erythroblastopenia of childhood or Diamond Blackfan anemia. The aforementioned signs and symptoms suggestive of a congenital hemolytic anemia can be diagnostically useful in these patients.

Of note, the laboratory and clinical findings associated with unstable Hbs can be relatively nonspecific, overlapping with other etiologies of congenital hemolytic anemia, such as membranopathies (see Chapter 16), enzyme defects (see Chapters 17 and 18), and thalassemias (see Chapter 21). Indeed, their intrinsic transient nature renders many unstable Hbs difficult to detect, isolate, or study.[232,233] Thus globin gene sequencing should be performed to identify potential unstable Hb variants in any patient with unexplained hemolytic anemia.

Box 19-6 Polycythemia versus Erythrocytosis

Erythrocytosis is defined as increased concentration of blood erythrocytes, measured as the number of cells per volume, total hemoglobin concentration, or packed red cell volume (hematocrit). This can be the result of reduced plasma volume, typically caused by dehydration or polycythemia ("many cells"). *Polycythemia* describes an increase in the total quantity or mass of red blood cells in the body and is caused by numerous abnormalities, including reduced tissue O_2 delivery caused by high–O_2 affinity Hb variants (see Table 19-5).

Hb, Hemoglobin; *O_2,* oxygen.

Erythrocytosis: High–Oxygen Affinity Hemoglobin Variants

The Hb tetramer must bind and deliver O_2 properly in response to environmental conditions. Hb variants that increase the O_2 affinity of Hb typically inhibit O_2 delivery to tissues, which stimulates erythropoietic drive, causing erythrocytosis with a resultant ruddy complexion.[234] Note that although the terms *polycythemia* and *erythrocytosis* are often used interchangeably, they are not equivalent (Box 19-6). High–O_2 affinity Hb variants are associated with elevated EPO levels, distinguishing them from erythroid-cell autonomous mechanisms of erythrocytosis that are independent of EPO[4] (Table 19-5). Erythrocytosis caused by high–O_2 affinity Hb variants does not usually produce dangerous vaso-occlusive events, in contrast to myeloproliferative disorders such as polycythemia vera. Patients with erythrocytosis caused by high–O_2 affinity Hb variants are reported to have mistakenly received radioactive ^{32}P for presumed polycythemia vera.[4,6] Conditions of low ambient O_2, such as unpressured airplane cabins or exposure to high altitude, do not represent a risk to patients with high-O_2 affinity Hbs. In fact, such individuals are better equipped than an average person to handle such situations, because their Hbs bind O_2 avidly.[235] After giving birth, women with high–O_2 affinity Hb mutants exhibit no increases in morbidity or mortality for mother or child, even when the mother's variant Hb has higher O_2 affinity than that of HbF.[236] This suggests that compensatory mechanisms other than the differences in O_2 affinity must exist in pregnancies to help deliver O_2 to the fetus.

Cyanosis: Low–Oxygen Affinity and M-Type Hemoglobin Variants

Cyanosis is defined as a bluish discoloration of the skin and mucous membranes as a result of excessive levels of deoxy-Hb. In general, cyanosis is either central, involving the core, lips and tongue, or peripheral, involving the extremities. Central cyanosis usually becomes apparent at about 2 to 5 g/dL of deoxy-HbFe(II), 1.5 to 2 g/dL of

TABLE 19-5 Differential Diagnosis of Polycythemia

Classification	EPO Level	Etiology
Primary (erythrocyte intrinsic)	Low	Myeloproliferative disorders (polycythemia vera) EPO receptor mutations

*Abnormalities discussed in detail in this chapter.

met-HbFe(III), or 0.5 g/dL sulfhemoglobin (sulf-Hb), and can be more difficult to detect in individuals with darker skin pigments. Cyanosis is caused by many conditions affecting numerous organ systems[237] (Box 19-7), most commonly heart or lung problems. However, chronic cyanosis can also be caused by globin mutations that reduce Hb O_2 affinity or favor oxidation of Hb iron to the Fe(III) (met-Hb) form (M Hbs), which cannot bind O_2. Cyanosis caused by these Hb variants is usually associated with normal arterial O_2 saturation, in contrast to most other etiologies, which induce arterial hypoxia.

M-type Hbs cause the blood to appear chocolate brown because of characteristic light absorbance properties of met-Hb (visible peaks at 510 and 630 nm), which looks brown in solution. This coloration forms the basis for diagnostic testing (see Clinical Laboratory Tests to Identify Hemoglobin Variants). The variant HbM Iwate, first observed more than 200 years ago in Japan, was described as *black blood* or *hereditary nigremia.*[238-241] Clinically, the M Hb variants must be distinguished from methemoglobinemia induced by drug and chemical exposures, as well as genetic and developmental abnormalities in the erythrocyte met-Hb reduction system (Table 19-6).

In contrast to many disorders associated with cyanosis and/or methemoglobinemia, low–O_2 affinity and M Hb variants are not usually life- or health-threatening, although they can produce cosmetic effects that are deleterious to patients. As stated by Bunn and Forget, "the primary reason for establishing the diagnosis [of M Hbs] is to prevent iatrogenic misadventures that might arise under the mistaken impression that the patient has a cardiac or pulmonary disorder."[5] Thus establishing the correct diagnosis of low–O_2 affinity and M Hbs reduces the potential risk for unnecessary and potentially dangerous medical procedures such as cardiac catheterization for presumed cyanotic heart defects. For example, Bunn and Nagel discuss a 1-week-old infant who underwent a Blalock procedure because of pseudotruncus arteriosus.[4] Only when a family study was completed many years later was the individual identified as a carrier of Hb M Boston. Crowley et al. described a newborn infant of healthy appearance in whom cyanosis was caused by a low–O_2 affinity Hb variant.[242] The patient received aggressive medical support including mechanical ventilation and arterial catheterization that, in retrospect, was unnecessary. Her father also exhibited cyanosis at birth, which prompted an extensive workup that included a liver biopsy. In general, distinguishing low–O_2 affinity and M Hb variants from more dangerous conditions can be achieved through straightforward clinical assessment and laboratory testing. However, diagnostic dilemmas can occur as noted, particularly in newborns and infants where the potential for more common life-threatening situations must be addressed urgently and the clinician does not have the benefit of extended observation.

Ontogeny of Globin Gene Expression Influences the Clinical Presentation of Hemoglobin Variants

The α- and β-like globin gene families are regulated temporally during fetal and postnatal life, which influences

TABLE 19-6 Differential Diagnosis of Congenital Methemoglobinemia

Class	Description
Type I	Erythroid cytochrome b5 reductase deficiency
Type II	Total cytochrome b5 reductase deficiency

the timing at which Hb variants first manifest clinical symptoms (see also Chapter 1). HbF ($\alpha_2\gamma_2$) is the predominant form during late fetal life. Over several months after birth, expression gradually switches to HbA ($\alpha_2\beta_2$).[243] Thus symptomatic mutations affecting α or γ globins present prenatally or at birth, whereas the symptoms of β-globin mutations are typically delayed until a few months after birth. Importantly, γ-globin gene mutations that are apparent at birth, most typically reflected by cyanosis or hemolytic anemia, usually abate over a few weeks as Hb production switches from F ($\alpha_2\gamma_2$) to A ($\alpha_2\beta_2$). Examples include HbF Toms River and HbF Poole, which are discussed later in this chapter. In contrast, symptoms associated with α- or β-chain variants persist throughout life.

Clinical Laboratory Tests to Identify Hemoglobin Variants

Several routine blood tests are used to identify and characterize Hb variants (Table 19-7). Most of these methods, including electrophoresis, ultraviolet (UV)-visible light spectroscopy, and O_2 association studies, have been used for decades. These methods are reliable and relatively inexpensive. However, many of these tests are becoming increasingly unavailable for routine clinical testing. Newer technologies such as deoxyribonucleic acid (DNA) sequencing and mass spectrometry are now used increasingly to characterize Hb variants. These tests are now becoming less expensive and importantly, can pinpoint causative mutations in the globin-gene DNA or protein amino acid sequences. However, they do not reveal the functional effects of the mutation. The most comprehensive understanding of Hb variants comes from combined clinical observation, functional testing, and mutational analysis. Commonly used tests are reviewed in this section.

Physical Methods of Hemoglobin Separation

Many amino acid substitutions alter the physical properties of variant Hbs, allowing them to be distinguished by electrophoresis or chromatography. These methods examine the mobility of α1β1 dimers or individual globin subunits. Typical standards include normal Hbs A, F, and A_2, as well as the common variants S and C. Some Hb variants exhibit distinct migration patterns in these assays, although many are "electrophoretically silent." Unstable Hbs often appear as a diffuse band or, in some circumstances, simply as precipitated material at the gel origin.[244] This finding probably arises from partial denaturation of Hb molecules during electrophoresis or manipulation of the hemolysate. Historically, cellulose acetate and citrate agar electrophoresis were most commonly used to detect variant Hbs. Current clinical testing usually employs more sensitive techniques such as isoelectric focusing and HPLC. These methods are now used for routine neonatal screening in North American and European countries to identify common hemoglobinopathies.[245,246] Rare Hb variants can also be identified coincidentally through neonatal screening, sometimes necessitating follow-up testing to ascertain their clinical significance.

Oxygen Equilibrium Binding Curves

In this test, Hb in whole RBCs or hemolysate is deoxygenated and then exposed to gradually increasing P_{O2} with simultaneous measurement of percent (%) HbO_2 saturation. Results are plotted graphically as % HbO_2 saturation versus O_2 pressure (Fig. 19-16). The P_{O2} at which normal HbA becomes half-saturated (P_{50}) is 26 mm Hg using undialyzed hemolysate at pH 7.2,[247] and the shape of the saturation curve is sigmoidal, reflecting cooperative O_2 binding (see Cooperative Oxygen Binding). High–O_2 affinity variants become saturated at

TABLE 19-7 Laboratory Tests for Hemoglobin Variants

Test Category	Variant Types	Test Descriptions
Physical Hb separation	Any	Cellulose acetate or citrate agar electrophoresis Isoelectric focusing HPLC
O_2 equilibrium curve (see Fig. 19-13)	High– and low–O_2 affinity variants, M Hbs	Vary hemolysate exposure to O_2 and/or allosteric regulators (H^+, pH, 2,3-DPG)
UV-visible light spectroscopy	Any, especially M Hbs	UV-visible spectroscopy yields characteristic spectra for different M Hbs
Hb stability	Unstable	Heat, isopropanol, mechanical agitation, zinc acetate
Heinz body staining	Unstable	Supravital staining of red cells for precipitated globins
DNA sequencing	Any	Direct sequencing of patient's globin genes
Mass spectrometry	Any	Obtain amino acid sequence of patient's Hb

2,3-DPG, 2,3-Diphosphoglycerate; *DNA,* deoxyribonucleic acid; *H^+,* hydrogen cation; *Hb,* hemoglobin; *HPCL,* high-performance liquid chromatography; *UV,* ultraviolet.

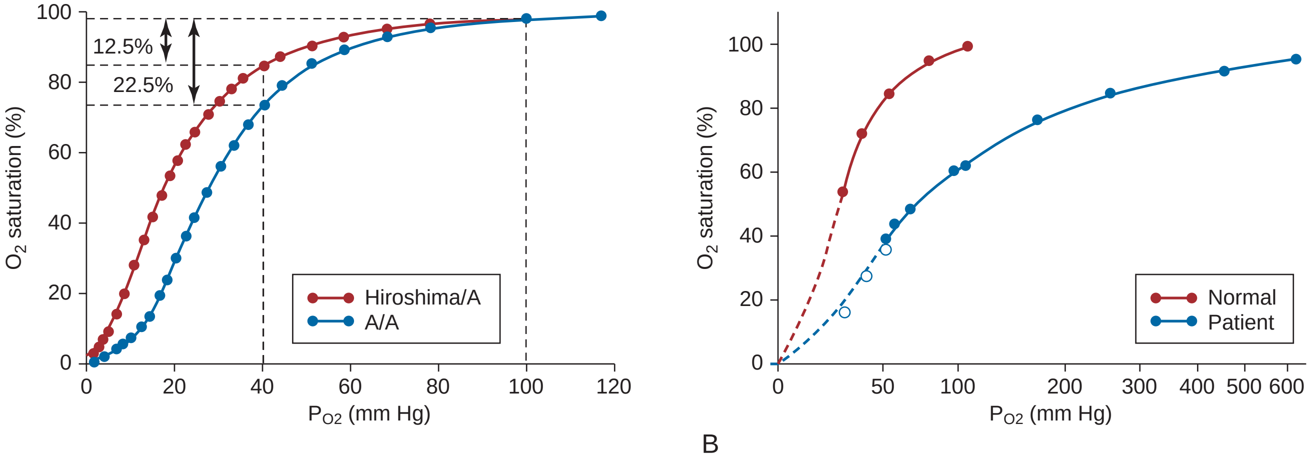

Figure 19-16 Oxygen saturation curves from normal and variant Hbs. **A**, Oxygen saturation curves of red blood cells from a healthy individual (Hb A/A) and one who is heterozygous for the high–O_2 affinity variant Hb Hiroshima (Hb Hiroshima/A). Oxygen pressure is plotted against oxygen saturation. *Vertical dotted lines* mark the typical P_{O2} of the lungs (100 mm Hg) and tissues (40 mm Hg). *Horizontal dotted lines* mark O_2 extraction (lungs minus tissues) in normal red cells (22.5%) and the reduction observed in high–O_2 affinity red cells (12.5%). **B**, Hb O_2 equilibrium curves of red cells from a healthy person *(Normal)* and those from a person heterozygous for the low–O_2 affinity variant Hb Kansas *(Patient)*. P_{O2} (in mm Hg) is plotted against percent O_2 saturation. Note that the curve for Hb Kansas is right-shifted, causing a higher P_{O2} at which half of the hemoglobin is oxygenated (P_{50}). *(**A**, From Hamilton HB, et al: Hemoglobin Hiroshima [beta-143 histidine→aspartic acid]: a newly identified fast moving beta chain variant associated with increased oxygen affinity and compensatory erythremia.* J Clin Inv *48:525–535, 1969; **B**, From Reissman, et al: A human hemoglobin with lowered oxygen affinity and impaired heme-heme interactions.* J Clin Inv *40:1826–1830, 1961.)*

lower O_2 pressures and demonstrate a left-shifted O_2 equilibrium curve (see Fig. 19-16, *A*). Mutations that reduce O_2 affinity cause a right shift, because less Hb is oxygenated at a given P_{O2} (see Fig. 19-16, *B*). Because cooperative regulation of Hb is an important functional property (see Allostery and the Perutz–Monod, Wyman, Changeux Model of Hemoglobin Function), investigation of O_2 affinity responses to allosteric regulators, particularly 2,3-DPG or H^+ (pH changes), can provide insight into the structural causes of the observed phenotypes.

Ultraviolet-Visible Wavelength Light Spectroscopy

The heme moiety of Hb absorbs visible light and therefore is responsible for the distinct color of the protein. Alterations in the electron configuration of heme, such as those caused by changes in the iron oxidation or ligand states, produce characteristic color changes that are reflected in the visible light absorption spectrum. These different absorbance peaks explain why HbO_2 (Fe[II]–O_2 heme) is red (two peaks at 541 and 577 nm but transmits red light at 600 nm), whereas deoxy-Hb (five-coordinate Fe[II] heme) is a darker purple-bluish color (one broad peak at 555 nm that absorbs some red light at 600 nm). Met-Hb (Fe[III] heme with a weakly coordinated H_2O) forms a characteristic absorbance peak at 630 nm, which forms the basis for its detection by cooximetry in the clinical laboratory and accounts for its brownish color. The M Hbs exhibit complex absorbance spectra containing the normal red peaks for wild-type HbO_2 subunits along with new ferric bands in the 600 to 630 nm region for the mutated met-Hb subunit. These spectra are readily distinguished from “normal” met-HbA formed by extrinsic abnormalities, such as deficiencies in the met-Hb reductase system or toxin exposures.[5] Visible light spectroscopy can also distinguish deoxy-Hb and met-Hb from sulf-Hb, a rare cyanotic condition in which environmental exposure to sulfur compounds causes a sulfhydryl to be added to the pyrrole B ring,[248] rendering sulf-Hb incapable of binding O_2.[249] Sulf-Hb has a characteristic peak at 620 nm, which is not altered significantly by reduction.

Pulse oximetry is used routinely to clinically assess blood oxygenation. This is a noninvasive spectrophotometric test that measures absorbance ratios for oxygenated (660 nm) and deoxygenated (940 nm) blood at these single wavelengths.[250] Since M Hbs and sulf-Hb alter light absorbance in unique ways across the visible spectrum, absorbance measurements calculated from these two discrete light wavelengths may be misleading for these conditions where pulse oximetry usually calculates high levels of deoxy-Hb (i.e., hypoxia), although arterial blood O_2 levels are normal. In this setting, analysis of Hb by light absorbance throughout the full visible wavelength spectrum can provide diagnostic information.

Hemoglobin Stability Testing

Hemolytic anemia results when erythrocyte stability is compromised. Unstable Hbs precipitate within cells and are deposited on the inner plasma membrane, making the erythrocyte rigid, brittle, and prone to lysis. Thus hemolytic anemia is associated with variants that destabilize Hb. Hb stability tests measure the propensity for Hb to denature upon exposure to various stresses including heat,[251] isopropanol,[252,253] mechanical agitation,[254,255] and zinc acetate.[256] In all of these tests, unstable variants denature at lower thresholds than normal Hb.

Examination of the Blood Smear

Erythrocyte morphology observed in Wright-Giemsa–stained blood smears from patients with unstable Hbs is

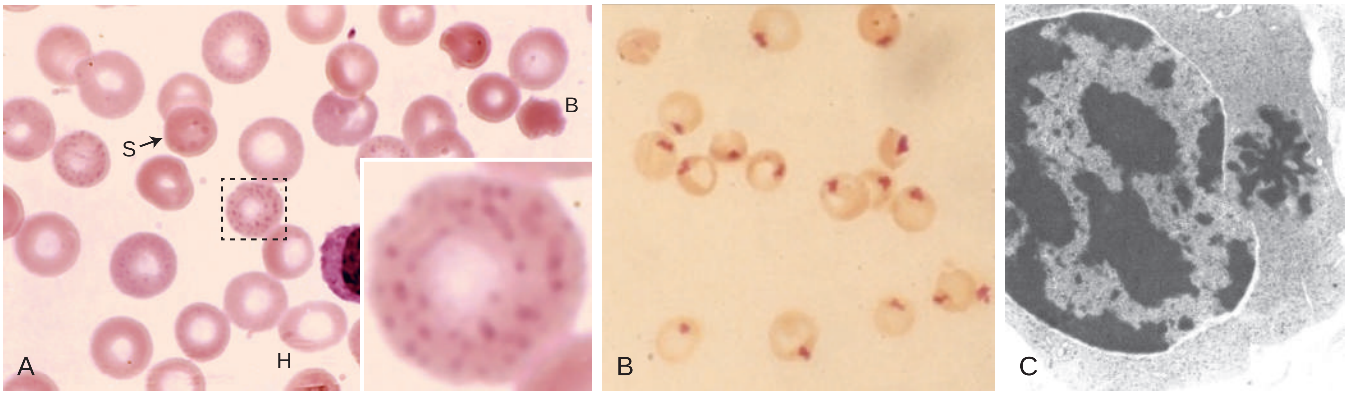

Figure 19-17 Abnormal blood smear findings in patients with unstable Hbs. **A**, Blood smear from a patient with Hb Nottingham (presplenectomy), stained with Wright-Giemsa. The inset shows an enlarged view of the boxed cell to illustrate basophilic stippling. Other abnormalities include hypochromic cells (*H*), spherocytes (*S*), and degmacytes ("bite" cells, *B*). **B**, Methyl violet stain illustrating erythrocyte Heinz bodies in a patient with an unstable Hb. **C**, Electron micrograph showing Hb precipitate in a bone marrow erythroid precursor from a patient with Hb Constant Spring. *(From Derry S, et al: Hematologic and biosynthetic studies in homozygous hemoglobin Constant Spring.* J Clin Inv *73:1673–1682, 1984;* ***A*** *and* ***B*** *Courtesy of Dr. Samuel Lux, Boston Children's Hospital.)*

variable depending on the nature of the mutation. Basophilic stippling, reflecting accumulated ribosomal RNA aggregates, is common (Fig. 19-17, *A*). Spherocytes, hypochromia, bite cells, blister cells, and altered red-cell size can also occur. All of these morphological abnormalities tend to be more prominent postsplenectomy and/or during hemolytic crisis.

The Heinz body test utilizes supravital stains to detect unstable precipitated globins within erythrocytes.[257-260] Heinz bodies are increased in the setting of unstable Hbs, oxidative damage, and thalassemias. They appear as irregular, pale purple inclusions, present as singular or grouped bodies that are often attached to the membrane[261] (see Fig. 19-17, *B*). Cells containing precipitated Hbs are rapidly removed by the spleen and therefore may be apparent only after splenectomy or by staining of bone marrow erythroblasts.[257,259,260] In patients who have not undergone splenectomy, Heinz bodies become more prominent after 24-hour incubation without glucose. Brilliant cresyl blue is a stain with mild oxidant activity that enhances the sensitivity of this test by causing precipitation of unstable Hbs. In contrast, methyl violet stains only preformed Hb precipitates without inducing their formation. When testing for Heinz bodies in hemolytic anemia, a sample of normal blood is run in parallel, because nonspecific staining can yield false-positive results. Unstable Hbs can also precipitate in bone marrow erythroid precursors, which can be detected by Heinz body staining or electron microscopy (see Fig. 19-17, C).

Biochemical Testing

Specialized biochemical tests can readily differentiate different causes of cyanosis.[4] A simple test to distinguish met-Hb from cardiopulmonary cyanosis or cyanosis caused by low–O_2 affinity Hbs is to expose blood from the patient to pure O_2. This should turn the purple deoxy-Hb in venous blood to bright red HbO_2. In patients with methemoglobinemia, sulfhemoglobinemia, or M Hbs, the blood will retain its brown color. The presence of an M Hb variant can then be distinguished from other causes of methemoglobinemia and sulfhemoglobinemia through the addition of potassium CN. Hemolysates containing "normal" met-Hb (with wild-type globin chains) will turn red immediately after addition of potassium CN. In contrast, those with M Hb variants often change color more slowly, although the rate of conversion varies with different M Hbs.[262] Sulf-Hb, an inert compound that does not react with CN, will not change color.[263]

Biochemical tests can also discern erythrocytosis caused by high–O_2 affinity variants from conditions caused by certain congenital enzyme deficiencies. At physiologic pH and temperature, comparing the O_2 affinity of whole red cells to their phosphate-free hemolysates readily differentiates whether a perturbation is the result of intrinsic Hb alterations or extrinsic causes, such as congenital deficiency of 2,3-DPG mutase. Variant Hbs will show altered O_2 affinity in both the hemolysate and whole red cells. In contrast, erythrocytosis resulting from a deficiency of an allosteric regulator of Hb (e.g., 2,3-DPG) will demonstrate high–O_2 affinity in whole cells and normal O_2 affinity in the hemolysate.

Specialized Testing

Historically, mass spectrometry, X-ray crystallography, and DNA sequencing have been used in research laboratory settings to confirm and characterize the biology of interesting Hb variants that were identified clinically using the methods described. However, DNA sequencing is becoming more convenient to perform at reduced costs. Directed analysis of globin genes is widely used to diagnose Hb variants in specific patients and in high-risk populations.[220,264,265] As noted in Identification of Hemoglobin Variants, whole exome and genome sequencing, which are increasingly being performed for a variety of reasons, are likely to discover incidental globin gene mutations of varying significance.[222,266] Mass spectrometric analysis has been used extensively to identify amino acid alterations in globin proteins,[267,268] although DNA sequencing is becoming a more common test to diagnose

Hb variants. However, mass spectrometry remains useful, particularly in unusual cases where posttranslational modifications of globin chains are suspected to contribute to disease pathology[242,269] (see the discussion on Hbs Bristol-Alesha and Toms River in Hemoglobin Variants that Cause Multiple Biochemical Alterations). Crystallographic analysis has been an extremely fruitful approach to determine how amino acid substitutions alter the structure and function of Hb variants.[270-272]

Clinical Management of Patients with Hemoglobin Variants

Management issues arising from unique circumstances associated with specific Hb variants were previously discussed (see *Clinical Manifestations of Hemoglobin Variants Reflect Their Physiological Effects*). In contrast to sickle-cell disorders and many forms of thalassemia, most Hb variants are either asymptomatic or produce mild clinical effects that require only counseling and supportive care. Indeed, one important reason to diagnose and characterize rare Hb variants is to prevent unnecessary invasive procedures.

Hemolytic anemia caused by unstable Hb variants is associated with a wide range of clinical severity, depending on the nature of the mutation and environmental factors such as infection and oxidant exposure. In moderate cases, folic acid supplementation and/or intermittent RBC transfusion during hemolytic crises may be required. The most severe unstable Hbs, including the “hyperunstable” variants (discussed later in this chapter), can cause severe anemia requiring regular transfusions with attendant problems, including iron overload, risk of infection, and alloimmunization. For severely affected patients, splenectomy may be beneficial but must be weighed against potential toxicities such as increased risk for infection and thrombosis,[273,274] including priapism.[275,276] Rose and colleagues reported clinical improvement after hydroxyurea treatment to induce HbF in two cases of hemolytic anemia caused by unstable Hb variants.[277] In the most severe refractory cases of Hb variant–associated hemolytic anemia, bone marrow transplantation may be indicated.

Most patients with high–O_2 affinity Hbs require no treatment. Rarely, erythrocytosis caused by high–O_2 affinity Hbs can cause symptoms reflecting vaso-occlusion, including headaches,[234] angina,[278] or hypoxemia.[279] In these cases phlebotomy may be considered, although there are conflicting reports on the benefits.[280,281] Low–O_2 affinity Hbs almost never require treatment, because tissue oxygenation is adequate. In fact, one Hb variant (Hb Hope identified in a Tunisian athlete) is reported to increase performance by enhancing O_2 delivery.[282] Publicly available databases (i.e., the Globin Gene Server[12,13]) can serve as valuable resources because many rare Hb variants have been previously encountered and described.

Pathophysiology of Hemoglobin Abnormalities

This section reviews the biochemical mechanisms by which globin-gene mutations alter Hb function and physiology (see Table 19-3). Selected examples of Hb variants that illustrate general mechanistic principles are discussed in detail and listed in Table 19-8. Standard Hb variant nomenclature denotes the mutated chain, amino acid residue number, residue position within the helical globin fold, and substituted amino acid residue type (normal→substituted), for example, β92 (F8) His→Tyr (Hb M Hyde Park).

Assembly of Mutant Hemoglobins

The relative proportions of normal and mutant Hbs in the red cells of heterozygotes provides insight into Hb assembly and hemoglobinopathies.[283,284] Most β-globin variants caused by missense mutations are synthesized at the same rate as normal β globin (βA) and have normal stability. Therefore heterozygotes might be expected to have equal amounts of normal and mutant Hbs, at least the stable ones. However, Bunn, McDonald, and colleagues found that the proportions of normal and mutant globin chains in heterozygotes vary according to the charge difference conferred by the mutation.[285,286] Figure 19-18 compares the proportion of different stable variant β chains to βA in heterozygotes. Note that the more positively charged mutants, such as Hbs S, C, D Los Angeles, and E, account for significantly less than half of the total Hb in heterozygotes. The proportions are further reduced in the setting of α-thalassemia, when the α chain is limiting for Hb assembly. In contrast, many of the negatively charged variants are present in amounts exceeding that of βA. The proportion of mutant Hb was further increased in two heterozygotes for negatively charged mutants (HbJ Baltimore or HbJ Iran) combined with α-thalassemia. These studies suggest that globin subunit surface charges contribute to the rate of Hb tetramer assembly. Since normal α chains exhibit a net positive charge (basal isoelectric point at pH 8.72), they bind more rapidly to β-variant chains with increased negative charge. This electrostatic model for Hb assembly is supported by in vitro mixing experiments[287,288] and also has clinical implications. For example, differences in rates of Hb assembly explain why patients with HbSC disease have about 50% HbS and 50% HbC in their RBCs, whereas patients with HbAS (sickle cell trait) have about 35% to 40% HbS and 60% to 65% HbA. The electrostatic model also can account for differences in levels of HbA_2[284] and HbF[289,290] that accompany certain hematologic disorders.

Unstable Hemoglobin Variants

Unstable globins tend to denature and precipitate, forming Heinz bodies that damage erythrocytes through several mechanisms and cause hemolytic anemia. Examples are listed in Table 19-8, and the location of variant amino acid residues are denoted in Figure 19-19. For example, unstable globins can release heme, unfold, and interfere with other cellular proteins through hydrophobic interactions. Partially denatured oxidized Hbs can also form hemichromes, which are low-spin, unstable forms of ferric Hb in which the sixth coordination position of iron is aberrantly bound by globin amino acids via hydroxyl or histidyl groups.[291-296] Hemichromes are unstable and lose hemin, which in turn readily produces ROS.[297] Denatured, hemichrome-associated globins and hemin–globin precipitates can associate with the plasma membrane,[298,299] causing peroxidation and cross-linking of membrane

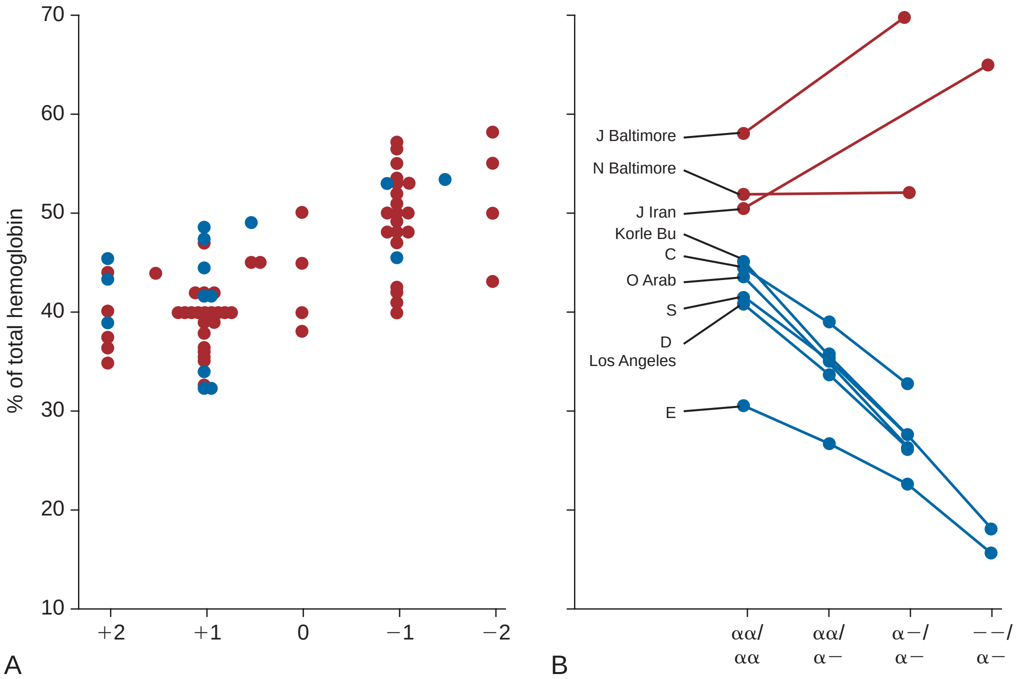

Figure 19-18 Charge affects Hb folding and expression. **A**, Effect of charge on the proportion of abnormal Hb in individuals heterozygous for 72 stable β-globin variants. Each point denotes a mean value for a given variant. *Blue points* denote high-resolution chromatography measurements. Histidine residue substitutions were scored as a change of one-half charge. The "–1" group differs significantly from the "+1" group ($P < .001$) and from the "0" group ($P < .05$). **B**, Effect of α-thalassemia on the proportion of six positively charged β-chain variants *(blue)* and three negatively charged variants *(red)*. *(A, From Huisman TH: Percentages of abnormal hemoglobins in adults with a heterozygosity for an alpha-chain and/or a beta-chain variant.* Am J Hematol *14:393–404, 1983; B, From Bunn HF, McDonald MJ: Electrostatic interactions in the assembly of haemoglobin.* Nature *1306:498–500, 1983 and Rahbar S, Bunn HF: Association of hemoglobin H disease with Hb J-Iran [beta 77 His→Asp]: impact on subunit assembly.* Blood *70:1790–1791, 1987.)*

proteins including Band 3.[231,300-305] This process can also inhibit membrane transport processes.[231,306,307] Precipitated globins may also interfere with general protein quality-control mechanisms that are required for normal erythropoiesis.[31]

Association of precipitated globins with plasma membranes can also inhibit the deformability of erythrocytes. These changes causes the cells to be "pitted" and/or captured by the spleen, the organ responsible for maintaining erythrocyte quality control.[306] *Pitting* refers to the mechanism by which Heinz bodies along with a portion of the overlying plasma membrane are excised from erythrocytes by splenic macrophages. Over time, repeated pitting and membrane loss converts biconcave erythrocytes into spherocytes, ultimately producing a rigid remnant that is eliminated from the circulation.

Figure 19-19 Diagram of the α1β1 dimer showing amino acid substitutions in unstable Hb variants discussed in this chapter. See also Table 19-8. **A**, *Spheres* indicate the locations (Cα positions) and amino acid residue number of substitutions giving rise to the unstable Hb variants. Positions are color coded as indicated according to abnormal biochemical/structural properties conferred by the substitution. **B**, Some variants in α globin (substituted amino acids shown in *blue*) inhibit interactions with the α-globin chaperone, AHSP, and with β globin at the α1β1 interface. Mutations of α99 (G6) Lys *(red)* destabilize the interaction of α globin with AHSP but not with β globin.

Altered Secondary Structure of Hemoglobin Subunits. More than 75% of Hb is α helical.[17,308] This structure is particularly susceptible to disruptions by proline substitutions because proline lacks an amide proton and so does not contribute to the regular hydrogen bonding pattern, and steric hindrance from the proline side chain requires the helix to kink. Indeed, about 15% of mutations responsible for unstable Hbs involve the introduction of a proline residue into the middle of an α helix.[4] For example, Hb Brockton (β138 [H16] Ala→Pro) results in an unstable Hb and mild hemolytic anemia[309,310] (see Fig. 19-19, *A*, *green sphere*; see also Fig. 19-17, *A*). X-ray crystallographic analysis showed that this mutation causes structural perturbations localized only in the vicinity of helix H.[310] Accordingly, Hb Brockton does not exhibit altered O_2 binding affinity or electrophoretic mobility shifts. In contrast, Hb Singapore (α_1 or α_2 141 [HC3] Arg→Pro) contains a substituted proline that does not destabilize the molecule because the substitution occurs at α141 Arg, the last amino acid in the chain, which is not part of an α helix[311] (see Fig. 19, *A*, *green sphere*). As a result, this latter mutation has no clinical consequences. Hb Singapore was discovered through its altered electrophoretic mobility during the workup of a child with anemia that was eventually attributed to iron deficiency.

Altered Tertiary Structure of Hemoglobin Subunits. As described in sections on hemoglobin structure, mutations that alter the polarity or size of buried hydrophobic residues can destabilize the tertiary structure. For example, HbF Poole ($^G\gamma$130 [H8] Trp→Gly) was identified in a newborn with hemolytic anemia.[312] The replacement of the larger aromatic side chain with glycine, which has no carbon side chain, renders this globin unstable by creating a cavity in the middle of the γ subunit. As the mutation occurred within a γ-globin gene, the condition resolved spontaneously after the first few months of life. Information on protein stability is available from the Globin Gene Server[12,13] for 29 Hb variants with X_{aa}-to-Gly mutations in α or β Hb chains. Of these, eight are annotated as unstable variants, with six being Gly replacements of Val or Trp side chains in the globin interior. All 21 variants with normal to mildly unstable phenotypes have substitutions on the surface of the α/β-globin chain.

Conversely, substitution of the conserved pair of Gly residues at positions B6 and E8 (see sections on hemoglobin structure) with more bulky residues can also destabilize Hb. Variants at positions β24 (Hb Moscva β24 [B6] Gly→Asp[313] and Hb Savannah β24 [B6] Gly→Val[314]), β64 (HbJ Calabria [E8] Gly→Asp[315]) and α59 (Hb Zurich-Albisrieden [E8] Gly→Arg[316]) destabilize the globin fold, giving rise to unstable Hb phenotypes, presumably by forcing the B and E helices slightly apart. The unstable Hb Savannah variant (β24 [B6] Gly→Val), which causes hemolytic anemia,[314] supports the conclusion that destabilization is the result of steric effects and probably not changes in electrostatic interactions.

Altered Heme–Globin Interactions. Mutations that impair interaction with the heme group also produce unstable Hbs (see Fig. 19-19, *A*, *purple spheres*). There are several ways in which globin mutations can interfere with heme incorporation. For example, introduction of a charged side chain into the heme pocket where a nonpolar side chain normally exists occurs in unstable Hbs Borås (β88 [F4] Leu→Arg),[317] Olmsted (β141 [H19] Leu→Arg),[275,318,319] and Himeji (β140 [H18] Ala→Asp).[320] Unstable Hb variants may also occur via deletions of residues that directly interact with heme, such as Hb Gun Hill (β91 [F7]–95 [FG2] Leu-His-Cys-Asp-Lys→0).[321,322] This class of variants also includes nontyrosine substitutions of the proximal (F8) or distal (E7) histidines, which in the wild-type subunits either directly coordinate the heme iron or donate a stabilizing H-bond to bound dioxygen, respectively (see Fig. 19-19, *A*, *orange spheres*). Hb Zurich (β63 [E7] His→Arg) is a distal histidine substitution that both destabilizes the molecule and alters interaction with allosteric regulators[323,324] (see Hemoglobin Variants that Cause Multiple Biochemical Alterations). Hb Zurich exhibits enhanced susceptibility to drug-induced oxidation, because the charged guanidino group of the Arg E7 side chain swings out of the distal pocket, exposing the distal pocket to water, and affected patients can experience sulfonamide-induced hemolytic anemia.[325,326] Tyrosine substitutions of the proximal and distal His residues, which cause increased levels of met-Hb (see Methemoglobin [M Type] Hemoglobin Variants), can also be destabilizing.

Altered Globin Subunit Interactions (Quaternary Structure). Globins typically exist as tightly associated α1β1 dimers or tetramers that are formed through α1β2 interactions (see Hemoglobin Quaternary Structure). Hb monomers (α) or homotetramers (β_4) are unstable. Therefore substitutions of amino acids that participate in α1β1 association to form the initial dimer can cause the accumulation of unstable free subunits (see Fig. 19-19, *A*, *blue spheres*). For example, Hb Philly (β35 [C1] Tyr→Phe) prevents formation of a hydrogen bond that normally occurs between β35 Tyr and α126 Asp at the α1β1 interface.[244] Electrophoretic analyses of Hb Philly hemolysate demonstrated free α chains and an abnormal "smear" indicative of denatured Hb. Other examples of Hb variants that impair globin chain assembly by altering the α1β1 interface include Hb Peterborough (β111 [G13] Val→Phe),[327] Hb Stanmore (β111 [G13] Val→Ala)[328] and HbJ Guantanamo (β128 [H6] Ala→Asp).[329] Hb Khartoum (β124 [H2] Pro→Arg) contains a substitution at the α1β1 interface that is mildly destabilizing in vitro.[311,330] This variant was discovered incidentally and does not usually cause clinical symptoms in isolation, but it can exacerbate concurrent thalassemia.[331]

Disrupted Hemoglobin–Alpha Hemoglobin Stabilizing Protein Interactions. Some α-globin gene mutations that disrupt the α1β1 interface also inhibit binding of α globin to the AHSP, which is a molecular chaperone that binds and stabilizes free α-globin chains to facilitate efficient and correct HbA synthesis.[332,333] These variants include Hbs Prato (α_1 or α_2 31 [B12] Arg→Ser),[334] Lombard (α_2 103 [G10] His→Tyr),[335] Contaldo (α_1 or α_2 103 [G10] His→Arg),[336] Foggia (α_2 117 [GH5] Phe→Ser),[337] Groene

Hart (α_1 119 [H2] Pro→Ser),[338-341] and others[342,343] (see Fig. 19-19, *B*, *blue sphere*). Certain α-globin variants with amino acid substitutions at position α99 Lys, including Hb Turriff (α_1 or α_2 99 [G6] Lys→Glu)[219] and Hb Beziers (α_1 99 [G6] Lys→Asn),[344] bind β globin normally but exhibit impaired interaction with AHSP and may be mildly destabilizing (see Fig. 19-19, *B*, *red sphere*).[33,34,343] Antitermination mutations may also destabilize α globin by impairing its binding to AHSP.[345]

Elongated Hemoglobin Variants

Antitermination and frameshift mutations that extend the open reading frame beyond the normal carboxyl terminus of the globin chain yield unstable proteins that are underrepresented in the hemolysate of affected patients. The most prevalent example is Hb Constant Spring (α_2 142 [HC3] Stop→Gln), caused by an antitermination mutation at the α_2 stop codon.[346-349] Hemolysates contain about 5% variant globin that is elongated by 31 amino acids (each α-globin chain in an HbA tetramer is normally present at 25%). Hb Constant Spring erythroblasts and reticulocytes contain cytoplasmic inclusions, similar to what occurs in β thalassemia and some hyperunstable Hb variants (see Fig. 19-17, C).[350] In addition, abnormal ribosome entry past the termination codon into the 3′ untranslated region of Hb Constant Spring mRNA displaces RNA-stabilizing proteins from this region, causing mRNA degradation.[350-353] For these reasons, Hb Constant Spring contributes to α-thalassemia syndromes. When combined with two α-globin deletional alleles ($—/\alpha^{CS}\alpha$), this variant produces a relatively severe hemoglobinopathy in which β_4 (HbH) tetramers accumulate and damage erythrocytes.[354] In pure heterozygous ($\alpha\alpha/\alpha^{CS}\alpha$) or homozygous ($\alpha^{CS}\alpha/\alpha^{CS}\alpha$) forms, Hb Constant Spring results in more severe anemia than occurs when the same α alleles are deleted ($\alpha\alpha/–\alpha$) or ($–\alpha/–\alpha$) as a result of the combined cytotoxic effects of the unstable Constant Spring protein and its mRNA instability.[355] Although it is most common in Southeast Asia, Hb Constant Spring is increasingly identified in other geographic regions, largely through global migration.[356] In fact, this variant was first discovered in a Chinese family living in Constant Spring, Jamaica.

Hb Cranston (β145 [HC3] + CT)[357] is an example of a β-globin chain elongation mutation. This mutation introduces a frameshift at the normal stop codon to generate a β chain that is extended by 11 amino acids, resulting in an unstable Hb tetramer with high–O_2 affinity and diminished cooperativity.[285,358] Affected patients exhibit compensated hemolytic anemia. Interestingly, studies on the structure of Hb Cranston occurred simultaneously with investigations aimed to determine the β globin mRNA 3′ untranslated sequence.[359] Cross-comparison mRNA-sequencing data between Hb Cranston and normal β globin allowed Bunn, Forget, and colleagues to more rapidly define normal β-globin gene structures and ascertain that the Hb Cranston mutation likely arose from nonhomologous crossover of two normal β-globin genes.

Hyperunstable Hemoglobin Variants

Some Hb variants are rapidly degraded after synthesis and therefore termed *hyperunstable* (see Fig. 19-19, *A*, *pink spheres*). Patients with these variants exhibit autosomal dominant "inclusion body thalassemia" resulting from both the precipitated variant globin and consequent chain imbalance with accumulation of the unaffected globin, which is unstable in its free form (particularly α chains).[360] This syndrome is characterized by significant anemia, splenomegaly, reticulocytosis, and a blood smear with prominent hypochromia, microcytosis, and basophilic stippling.[361,362] The bone marrow typically shows considerable erythroid hyperplasia and evidence of IE.

Weatherall, Thein, and colleagues characterized several hyperunstable mutations in the last exon (exon 3) of the β-globin gene, which produces the C-terminal portion of the protein.[361] All of the mutations were frameshifts or nonsense codons that produced relatively long proteins (>120 amino acid) with carboxyl-terminal truncations. The authors proposed that truncated globins causing dominantly inherited thalassemia are long enough to bind heme posttranslationally, which rendered them relatively resistant to proteolytic degradation, allowing for subsequent precipitation of heme-containing aggregates detected as Heinz bodies. Missense mutations can also cause hyperunstable Hb variants through extreme effects that are discussed earlier in this section.

Hyperunstable Hbs are usually difficult to detect at the protein level. Hb Hirosaki (α_2 43 [CE1] Phe→Leu) was discovered in a family with autosomal dominant hemolytic anemia.[232,233] After tests failed to identify a soluble variant Hb within erythrocytes, DNA sequencing identified a missense mutation affecting an amino acid in the α-globin heme pocket. Analogous mutations in β chains such as Hb Buccuresti-Louisville (β42 [CD1] Phe→Leu)[363,364] cause instability via reduced heme–globin interactions and accelerated autoxidation (see Altered Heme–Globin Interactions). These mutations affecting the "CD corner" of the heme pocket also show reduced O_2 affinity (see Hemoglobin Variants that Cause Multiple Biochemical Alterations).

Hb Terre Haute (β106 [G8] Leu→Arg) is another hyperunstable variant associated with severe Heinz body hemolytic anemia and globin-chain imbalance.[365] The Leu (G8) side chain is highly conserved in all mammalian Hbs and is an Ile in most Mbs. It is located in the interior of the heme pocket, and replacement with charge residues almost certainly prevents folding and heme binding. In initial studies of erythroid cells in patients, performed in 1979, abnormal Hb tetramers were not detected and peptide mapping of radiolabeled nascent globins identified a β112 (G14) Cys-to-Arg substitution, originally termed *Hb Indianapolis*.[257] However, the β112 Cys-to-Arg mutation was subsequently identified in unrelated individuals with much less severe disease. In 1991, reevaluation of the original pedigree by DNA analysis discovered a β106 Leu-to-Arg mutation, which was renamed *Hb Terre Haute*.[365] Most likely, incomplete tryptic cleavage of the abnormal β globin peptide in the earlier studies led to misidentification of the causative mutation. This work reflects the interesting historical point that many Hb variants were initially identified through laborious and technically challenging protein studies performed some time ago, before DNA sequence analysis of patient

globin genes was feasible. Reevaluation of these mutations though genetic testing has yielded some interesting surprises (see the discussion on Hb Bristol-Alesha in Hemoglobin Variants that Cause Multiple Biochemical Alterations).

High–Oxygen Affinity Hemoglobin Variants

In general, Hb variants that preferentially stabilize the R (oxygenated) state relative to the T (deoxygenated) state cause increased Hb O_2 affinity with a consequent decrease in tissue O_2 delivery (Table 19-8 and Fig. 19-20, *A*).[290] This decrease in delivery results in heightened EPO production and erythrocytosis. Increased O_2 affinity is indicated by a characteristic left-shifted O_2 equilibrium binding curve (see Figs. 19-13 and 19-16, *A*). Four classes of mutations enhance Hb O_2 affinity.

Altered α1β2 Interface. As described in the first part of this chapter, the T and R states are characterized by different sets of molecular interactions at the α1β2 interface. Mutations at the α1β2 interface that either stabilize the R state or destabilize the T state yield high–O_2 affinity Hb variants (see Fig. 19-20, *A*, *purple spheres*). Hb Chesapeake (α92 [FG4] Arg→Leu) was one of the first such Hb variants to be identified.[278] The propositus was an 81-year-old patient complaining of mild angina. He was found to have erythrocytosis, an abnormal Hb detected on electrophoresis, and a left-shifted Hb O_2 equilibrium curve. Affected relatives had similarly high hematocrit levels. Discovery and analysis of this family was remarkable at the time, because it demonstrated that an Hb variant could generate a distinct clinical syndrome. Whether the index patient's angina resulted from his erythrocytosis is unclear, however, as most high-affinity O_2 variants do not produce clinical consequences. The amino acid replacement in Hb Kempsey (β99 [G1] Asp→Asn) perturbs α1β2 interactions by preventing the formation of a hydrogen bond between β99 Asp and α42 Tyr, which normally stabilizes the deoxygenated low–O_2 affinity T state[366-369] (see Fig. 19-10).

Altered α1β1 Interface. Whereas mutations at the α1β2 interface have classically been associated with a perturbed T-to-R transition, variants affecting α1β1 interface residues have also been implicated in altering Hb cooperativity (see Fig. 19-20, *A*, *blue sphere*). For example, Hb San Diego (β109 [G11] Val→Met) was identified in a Filipino family with autosomal dominant erythrocytosis. The hemolysate demonstrated an increased O_2 affinity (P_{50}, 16.4 mm Hg; normal 26 mm Hg) with a normal Bohr effect and slightly reduced cooperativity.[234] Tryptic digestion and protein sequencing identified the amino acid replacement, which occurs on the α1β1 interface.[234] Crystallographic analysis of deoxy-Hb San Diego demonstrated that the substituted Met side chain produces steric effects that weaken the α1β1 interaction and destabilize the variant T state.[370]

Altered Cooperativity Through Modifications in Quaternary Structure. Hb Pôrto Alegre (β9 [A6] Ser→Cys) was identified during a population study as an abnormal electrophoretic variant in a healthy child (see Fig. 19-20, *A*, *light blue sphere*).[371] Hb Pôrto Alegre showed increased O_2 affinity and slightly decreased cooperativity. The sulfhydryl group of the mutant cysteine participates in intermolecular cross-linking reactions to form Hb Pôrto Alegre polymers.[371-374] This polymerization occurs during prolonged storage of blood samples and is suppressed in vivo, likely by increased erythrocyte glutathione reductase activity in subjects who carry the mutation.[375] Surprisingly, however, Hb Pôrto Alegre polymerization does not contribute to its altered O_2 binding characteristics.[373]

Altered Response to Allosteric Regulators. Several high-O_2 affinity Hb variants are caused by substitutions that inhibit interaction with allosteric activators such as 2,3-DPG (see Fig. 19-20, *A*, *brown sphere*), which normally binds between the β-globin chains to stimulate O_2 release (see *2,3-Diphosphoglycerate*). For example, in Hb Rahere (β82 [EF6] Lys→Thr) the invariant lysine in the

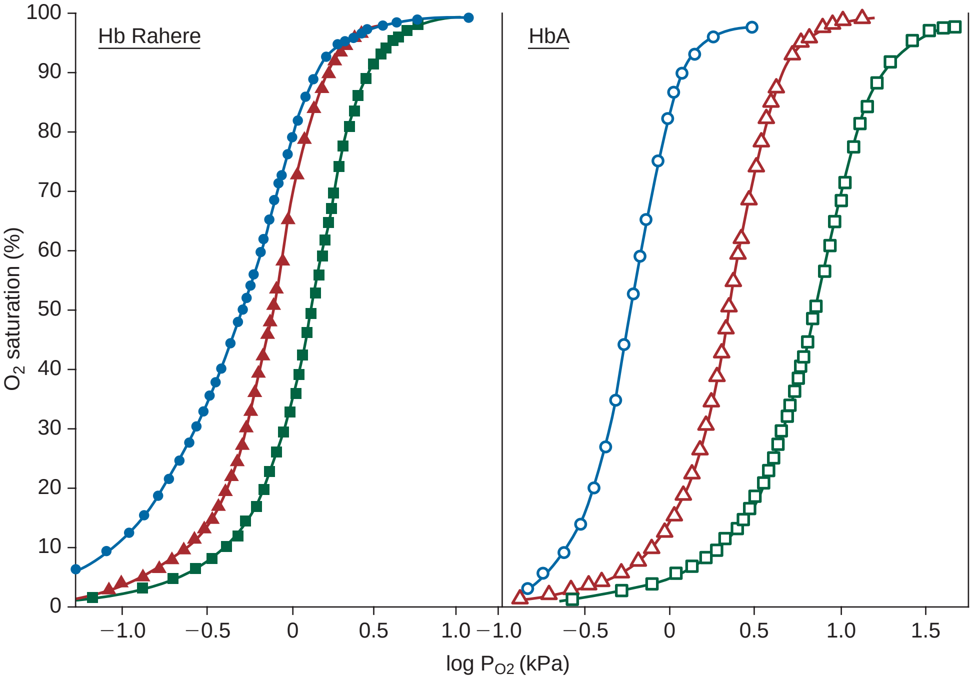

Figure 19-21 Hb Rahere is a high–O_2 affinity variant with impaired binding to 2,3-DPG. The graphs show O_2 dissociation curves for purified Hb Rahere *(closed symbols, left)* and HbA (*right, open symbols*) with no allosteric effector *(circles)* or in the presence of 2 mM 2,3-DPG *(triangles)* or 2 mM inositol hexaphosphate *(squares)*. Note that the right shift caused by organic phosphates is smaller in Hb Rahere versus HbA. *(From Lorkin PA, et al: Haemoglobin Rahere [beta Lys-Thr]: a new high affinity haemoglobin associated with decreased 2,3-diphosphoglycerate binding and relative polycythaemia.* Br Med J *4:200–202, 1975.)*

2,3-DPG binding site of β globin is replace by a smaller uncharged side chain, thereby reducing the affinity for this allosteric regulator.[376,377] Consequently, Hb Rahere exhibits blunted O_2 release in response to added 2,3-DPG in vitro.[376] The blunted response of this variant to 2,3-DPG is illustrated by the O_2 equilibrium curves shown in Figure 19-21. In vivo O_2 release in peripheral tissues is inhibited, resulting in erythrocytosis. Similarly, Hb Providence (β82 [EF6] Lys→Asn/Asp)[378,379] and Hb Helsinki (β82 [EF6] Lys→Met)[380,381] are high–O_2 affinity variants caused by different amino acid substitutions at the 2,3-DPG binding site on β82.

The C-terminal β146 His contributes significantly to the Bohr effect by forming a salt bridge with β94 Asp[272] (see Fig. 19-12 and *Carbon Dioxide Transport and the Bohr Effect*). This interaction is disrupted in several high–O_2 affinity variants with β146 substitutions, including Hb Hiroshima (β146 [HC3] His→Asp),[382,383,384,385] Hb York (β146 [HC3] His→Pro),[386] and Hb Cowtown (β146 [HC3] His→Leu)[272,387] (see Fig. 19-20, *A*, *green sphere*). Disruption of the Bohr effect contributes significantly to the high–O_2 affinity of these variants.

Low–Oxygen Affinity Hemoglobin Variants

Low–O_2 affinity variants preferentially stabilize Hb tetramer in the T (deoxygenated) state versus the R (oxygenated) state (see Table 19-8 and Fig. 19-20, *B*), typically resulting in cyanosis. Decreased O_2 affinity is indicated by a right-shifted O_2 equilibrium curve (see Figs. 19-13 and 19-16, *B*). Commonly mutated regions include the α1β2 interface, although mutations involving amino acid residues at the α1β1 interface have also been associated with low–O_2 affinity variants. Steric hindrance in the heme pocket can also reduce O_2 affinity.

Altered α1β2 Interface. Several low-O_2 affinity variants involve replacements at the α1β2 interface, which plays an important role in Hb cooperativity (see Fig. 19-20, *B*, *purple spheres*). Hb Kansas (β102 [G4] Asn→Thr) is a well-studied variant with low–O_2 affinity.[388-391] Affected individuals are markedly cyanotic, although clinically well. Replacement of β102 Asn at the α1β2 interface inhibits the formation of a hydrogen bond with α94 Asp that normally participates in R-state stabilization (see Fig. 19-10). A similar mechanism causes low–O_2 affinity in two other Hb variants with different substitutions at β102: Hb Beth Israel (β102 [G4] Asn→Ser)[392] and Hb St. Mandé (β102 [G4] Asn→Tyr).[393,394] Of note, one child with Hb Beth Israel exhibited cyanosis of the fingers, lips, and nail beds that was not detected by his parents. In fact, he had been disciplined in the past for having “dirty hands.” A surgeon who was about to perform herniorrhaphy discovered that the patient had cyanosis.[4]

Altered α1β1 Interface. β108 Asn lies near the α1β2 interface with its side chain projected into the solvent-filled central cavity. Substitution of β108 Asn with a negatively charged Asp Hb Yoshizuka (β108 [G10] Asn→Asp)[395] or positively charged Lys in Hb Presbyterian (β108 [G10] Asn→Lys)[396] alters interactions with the allosteric effectors Cl^- and H^+ (see Fig. 19-20, *B*, *light blue sphere*). Hb Yoshizuka has diminished Cl^- and Bohr effects, whereas Hb Presbyterian has enhanced Cl^- and Bohr effects.[397] Interactions with Cl^- and the Cl^--dependent Bohr effect are some of the least well-understood features of Hb.[68] Studies on Hb Yoshizuka and Hb Presbyterian proteins suggest that the distribution of positive and negative charges in the central cavity of the Hb tetramer can alter O_2 affinity and cooperativity, either directly through stabilizing the T state quaternary structure or indirectly through interactions with allosteric effectors.[397,398] However, the consequent low–O_2 affinity variant causes mild anemia resulting from globin instability but no apparent cyanosis.

Altered Charge at the Entrance to the Heme Pocket. Hb Chico (β66 [E10] Lys→Thr) displays a significantly reduced O_2 affinity, with normal cooperativity and anion sensitivity[399-401] (see Fig. 19-20, *B, dark purple sphere*). Biochemical studies suggest that the heme pocket in Hb Chico adopts a conformation that inhibits O_2 binding by reducing the reactivity of the iron atom even when ligands are in the active site.[400,401] Consistent with a mechanism involving an altered tertiary structure, isolated β Chico chains also have reduced O_2 affinity because of higher dissociation rate constants. In addition, the rate of CO binding to isolated β Chico subunits is at least twofold lower than that of wild-type β chains. One possible mechanism is that removal of the native positively charged Lys weakens interactions with the heme propionate, allowing the iron atom to move further out of the plane of the porphyrin ring, particularly in the T-state conformations.[389] This mutation also promotes autoxidation with consequent mild instability.

Methemoglobin (M-Type) Hemoglobin Variants

This class of Hb variants contains amino acid substitutions that alter the heme environment and stabilize the oxidized (ferric, Fe[III]) state over the reduced one (ferrous, Fe[II]), normally by coordination of the mutant side chain to the Fe(III) atom (see Table 19-8). Since oxidized met-Hb cannot bind O_2, patients exhibit cyanosis, although arterial oxygenation is normal. The blood usually appears brown in patients with met-Hb from numerous etiologies (see Table 19-6). However, the M Hb variants exhibit absorption spectra that are distinct from those for fully oxidized HbA and some unstable Hb variants with a tendency to oxidize, such as Hbs Saint Louis,[402] Bicetre,[403,404] I Toulouse,[405] and Seattle.[406] The differences are because of the presence of a native reduced subunit in the M Hb and also iron coordination to the mutant side chain. Comparative studies of the M Hbs have contributed greatly to understanding the biochemical properties of the heme iron, including its interactions with O_2 and ferric ligands. All of the M Hbs are caused by missense mutations in which the side chain of the substituted amino acid forms an abnormal coordination bond with ferric heme iron. Six out of the seven known M Hbs contain tyrosine replacements of either the α- or β-globin proximal (F8) or distal (E7) histidine residues present in the normal active site (Fig. 19-22).[407,408] In M Hbs, these mutations stabilize the ferric state to various extents via several mechanisms.

Heme Pocket Perturbations. In HbM Iwate (α_1 or α_2 87 [F8] His→Tyr), the proximal histidine is replaced by tyrosine[240,241] (see Fig. 19-22, *A*). Whereas Fe(III)-heme coordinated to the native proximal His F8 is readily reduced by met-Hb reductase, tyrosine (F8) coordination stabilizes the oxidized ferric state and decreases reactivity with the reductase system. This interaction also distorts the position of heme and helix F, creating a "green" α subunit with spectral properties similar to catalase, which also has a proximal Tyr ligand.[409-411] In native HbA, movement of the proximal His F8 and helix F away from the heme group stabilizes the deoxygenated T state and reduces the O_2 affinity of the native β-subunit partners. Hence substitution of the proximal His F8 side chain for a longer Tyr F8 in HbM Iwate also stabilizes the deoxygenated T state, possibly by positioning the F helix away from the heme group (see Fig. 19-22, *B*) and therefore also reduces O_2 affinity of the native β subunit within the mutant tetramer.[412,413] These biochemical and structural alterations underlie the lack of cooperativity and severe cyanosis in patients with HbM Iwate, where met-Hb levels can exceed 20% (normal <2%).[414] Nonetheless, O_2 delivery to tissue is not dramatically compromised because of the presence of native tetramers in heterozygotes and the native β chain in the mutant Hb.

HbM Saskatoon (β63 [E7] His→Tyr), which contains a distal His-to-Tyr substitution, is unusual amongst the M Hbs in that it is readily reduced by methemoglobin reductase (see Fig. 19-22, *C*). However, the heme in HbM Saskatoon is primarily hexacoordinated with Tyr E7 being in equilibrium between the protonated and deprotonated state, with the latter anionic state binding preferentially to Fe(III) but not to Fe(II) (see Fig. 19-22, *C and D*). These features presumably allow reduction.[415-417] Consequently, patients with HbM Saskatoon have lower levels of circulating met-Hb compared to those with HbM Iwate. HbM Boston (α58 [E7] His→Tyr) also substitutes the distal His with Tyr,[271,417,418] which again preferentially binds to the sixth coordinating position of the iron on the distal side of the porphyrin ring (see Fig. 19-22, *A*). In α subunits, Tyr E7 coordination can lead to breaking the Fe–His F8 bond in the T-state conformation. Thus the new Tyr E7–Fe(III) bond can alter the heme plane enough to disrupt the normal interaction between proximal His F8 and heme iron when strain is already present with significant consequences on the O_2 affinity of adjacent subunits (see Oxygen Binding Properties of M Hemoglobins). It should be noted that NO binding to α subunits stabilized in the T quaternary state can also lead to disruption of the His F8–Fe(II) bond.[165]

In contrast to all other M Hbs, HbM Milwaukee-I (β67 [E11] Val→Glu) does not involve a replacement of the proximal or distal His.[367,413,416,419,420] Instead, β67 Val is replaced by Glu in a position directly adjacent to bound O_2. The anionic carboxylate side chain in this variant coordinates directly to the sixth coordinate position of heme iron to stabilize the ferric state, and the proximal His F8 remains bound to the fifth coordinate position.[419,421] The proximity of this anionic residue to the iron atom facilitates the outer sphere autoxidation mechanism (see Autoxidation). As a result, the speed of spontaneous oxidation is dramatically increased, and the

Figure 19-22 Examples of M-type Hbs. **A**, Hb M variants with His-to-Tyr substitutions in the α chain. In HbM Iwate, the proximal His is replaced by Tyr, which is deprotonated and favors Fe(III) oxidation. In Hb M Boston, the distal His is replaced by Tyr, which coordinates bound O_2 and leads to disruption of the Fe–His F8 bond in the T-state conformation. These ferric α subunits are not reduced by met-Hb reductase. **B**, The heme pocket of wild-type Mb *(blue)* and an F8 (proximal) His-to-Tyr mutant (*orange*, PDB 1HRM), which serves as a model for HbM Iwate. The mutation causes displacement of helix F away from the heme moiety. **C**, HbM variants with His-to-Tyr substitutions in the β chain. In Hb Saskatoon (distal His→Tyr substitution) the hexacoordinate ferric iron can be reduced by met-Hb reductase, possibly owing to a transient protonation of Tyr E7. HbM Hyde Park replaces proximal His F8 with Tyr, resulting in heme loss and instability. **D**, Substituting the distal His E7 side chain in Mb for a larger Tyr E7 (*orange*, PDB 1MGN), as occurs in Hb Saskatoon, brings the Tyr hydroxyl group within binding distance of the iron, forming an hexacoordinate iron. Mb is used as a model for Hb subunits in **B** and **D**, whereas panels **A** and **C** are based on spectroscopy of mutant Hbs.[412,413,466]

met-Hb form of the mutant β subunit is markedly stabilized.

Weak Heme Attachment. Heme loss and consequent instability contribute to the pathophysiology of Hb M Hyde Park (β92 [F8] His→Tyr; see Fig. 19-22, *C*).[422-424] X-ray crystallography of deoxy-Hb Hyde Park showed 20% to 30% heme loss with consequent restructuring of nearby residues.[270] Electrophoresis detected a minor component (5%) of the hemolysate with altered mobility, which contained heme-deficient β Hyde Park chains.[425] Interestingly, although Hb Auckland (α97 [F8] His→Asn) mutates the same residue as HbM Hyde Park, the nontyrosine substitution causes accelerated heme loss, instability, and a mild compensated hemolytic anemia, but not methemoglobinemia because the ferric form of the mutant rapidly loses heme and denatures.[426]

Oxygen Binding Properties of M Hemoglobins. The two-state model for cooperativity predicts that the Hb tetramer will bind 2-3 molecules of O_2 in the low-affinity T (deoxy) state and then switch to the R (oxy) conformation (see Allostery and the Perutz–Monod, Wyman, Changeux Model of Hemoglobin Function). This facilitates cooperativity by increasing the O_2 affinity of the remaining deoxygenated globins. In M Hbs, the stabilized ferric heme groups in the mutant subunit cannot become oxygenated, but there are still two normal heme groups in the native subunits within any HbM tetramer. Interestingly the physiologic properties of HbM tetramers with His substitutions in α globin (HbM Boston and HbM Iwate) and β globin (HbM Saskatoon and HbM Hyde Park) differ. [413,424] The normal α subunits in HbM Saskatoon have increased O_2 affinity, and tetrameric HbM Saskatoon and HbM Hyde Park display significant cooperativity and Bohr effect when these two normal α chains are oxygenated.[424,427] In contrast, the normal β subunits in HbM α-globin variants have low–O_2 affinity, reduced cooperativity, and decreased Bohr effect.[424,428] HbM Iwate and HbM Boston remain in the low-affinity T state

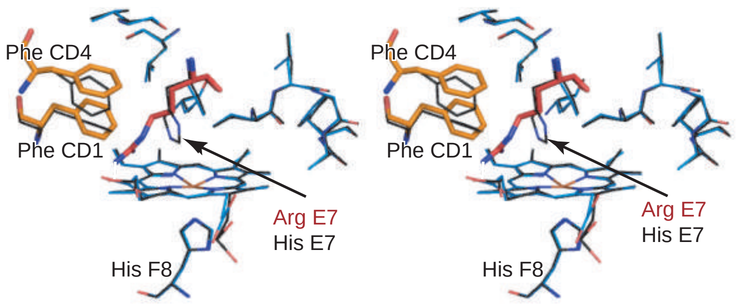

Figure 19-23 Hb Zurich is a variant with an altered heme pocket. Hb Zurich (β63 [E7] His→Arg). Stereo diagram model of the deoxy-βHb Zurich heme pocket *(blue)* overlaid with the wild-type βHb heme pocket (*black*, PDB 2DN2). This model, based on the structures solved by Phillips et al[323] and Tucker et al,[324] was generated with the macromolecular modeling program Coot[467] by mutating the distal His of deoxy-β (PDB 2DN2) to Arg. The distal Arg E7 *(red)* is oriented toward the CD corner, disturbing the position of Phe CD1 and Phe CD4 *(orange)*. The heme pocket entrance of Hb Zurich is much wider than normal, allowing increased access to ligands. However, unlike normal His E7, the mutant Arg is unable to stabilize bound O_2 via hydrogen bonding. *(From Thom CS, et al: Hemoglobin variants: biochemical properties and clinical correlates.* Cold Spring Harb Perspect Med *3:a011858, 2013.)*

even when the two normal β hemes are liganded, probably because of disruption of the α His (F8)–Fe(III) bond.[271,412,413,428] Moreover, these variant α subunits show extraordinary resistance to enzymatic or chemical reduction. The exact biochemical mechanisms responsible for all of these observed differences between for α and β M Hbs are not yet completely understood.

Hemoglobin Variants that Cause Multiple Biochemical Alterations

Not surprisingly, amino acid substitutions within critical regions of globin proteins can produce multiple effects (see Table 19-8). For example, HbE (β26 [B8] Glu→Lys), a common variant in Southeast Asia, contains an amino acid substitution that renders β chains mildly unstable in vitro with minimal clinical significance.[429-431] However, this mutation also creates an alternate splice site in the β-globin mRNA, leading to reduced synthesis of productive transcripts with resultant thalassemia.[432] HbE is particularly deleterious when co-inherited with a more severe β-thalassemic allele, a common occurrence in Southeast Asia.

Mutations that alter the heme pocket can also produce multiple biochemical effects. For example, the ability of HbM Hyde Park to generate an M-type and unstable Hb was discussed in the previous section. Other examples include Hb Bruxelles (β42 [CD1] Phe→0, deletion),[433,434] Hb Warsaw (β42 [CD1] Phe→Val),[435] Hb Hammersmith (β42 [CD1] Phe→Ser),[436] and Hb Buccuresti-Louisville (β42 [CD1] Phe→Leu),[363,364] which all cause both congenital Heinz body hemolytic anemia and cyanosis.

The latter effects are the result of severely reduced cooperativity, rapid rates of autoxidation with heme loss, and consequent unfolding of these unstable Hb variants.[434] After His F8, the Phe residue at the CD1 helical region is the most conserved residue in all known globins, from microorganisms to plants and animals, and its presence in a sequence is often used to define a globin fold.[423] The aromatic side chain is in direct contact with the heme group and helps orient the distal histidine and bound O_2. Thus its replacement with a smaller or polar amino acid markedly destabilizes the affected globin, altering its resistance to heme loss and also its O_2 affinity.

Hb Zurich (β63 [E7] His→Arg) is another interesting heme pocket variant.[230,323,324,437-440] In this variant, the distal His is replaced by Arg. Its large, highly polar side chain swings out of the distal heme pocket, and the positively charged guanidino group forms a salt bridge with a heme propionate (Fig. 19-23). This outward conformation enlarges the ligand binding pocket, destabilizes O_2 binding, and causes iron autoxidation through loss of stabilizing hydrogen bonds with the bound ligand as well as exposure to water (see Autoxidation). Affected individuals exhibit increased sensitivity to oxidants, including sulfa drugs, which more easily enter the enlarged heme pocket. Loss of the distal histidine markedly decreases O_2 affinity but has little effect on CO binding. As a result, individuals with Hb Zurich tend to have supranormal levels of HbCO, which protects the Hb molecule from oxidation and subsequent denaturation. Affected subjects who are cigarette smokers accumulate even higher levels of HbCO, which ironically tends to protect against hemolysis by inhibiting oxidation, heme loss, and unfolding of the mutant subunit. Thus "the pathology of a mutant protein is ameliorated by a normally toxic pollutant."[5]

Hb Köln (β98 [FG5] Val→Met), another heme pocket variant, is the most commonly diagnosed unstable Hb variant in the West.[7,441] This mutation disrupts the interactions between the proximal histidine and iron in the heme pocket, leading to enhanced heme dissociation.[442,443] Hb Köln is present at 10% to 25% of normal levels and has also been noted to have high–O_2 affinity. Affected individuals exhibit reticulocytosis, splenomegaly, and pigmenturia.[231] Of note, splenectomy is relatively contraindicated in Hb Köln, because erythrocytosis and thromboembolic complications, including priapism, have been linked to this procedure in affected patients.[276,444] Clusters of aggregates containing denatured Hb Köln and Band 3 have been shown to be immunogenic,[445] which may serve as a mechanism for rapid splenic clearance.[304,446]

Hb Bristol-Alesha (β67 [E11] Val→Met)[447,448] and HbF Toms River (γ67 [E11] Val→Met),[242] which contain the same amino acid substitution in β and γ chains respectively, represent interesting globin variants with multiple biochemical defects. Hb Bristol-Alesha was initially observed in patients with moderately severe hemolytic anemia. Structural analyses of the mutant protein in patient erythrocytes revealed a β67 Val-to-Asp substitution, predicted to render the protein unstable by introducing a highly charged polar residue into the hydrophobic heme pocket. However, subsequent DNA analysis of the same patient identified a Val-to-Met codon substitution.[448] The authors concluded that the mutant Met residue was converted to Asp posttranslationally, probably through oxidative mechanisms. More recently, the analogous variant was identified in fetal (γ) Hb (HbF Toms River).[242] The affected patient was a newborn with both cyanosis and anemia. DNA testing revealed the codon change (Val→Met at E11). Mass spectrometry of patient hemolysate indicated a mixture of variant γ globins containing either Met or Asp at position E11. Biochemical studies suggested that the HbF Toms River Met substitution produced a relatively stable variant γ globin that takes up O_2 too slowly to become saturated in the lungs, causing cyanosis. Its gradual posttranslational conversion to Asp destabilizes the molecule, causing denaturation and hemolytic anemia. This variant provides an example of how posttranslational modifications of variant globins can modify phenotypes. The reason that Hb Bristol-Alesha causes predominantly hemolytic anemia but HbF Toms River causes mainly cyanosis probably reflects different rates of Met conversion to Asp in the variant globin chains.

One recently identified example illustrates how multiple biochemical defects within a single molecule can produce unique phenotypes. Hb Jamaica Plain (β6 [A3] Glu→Val and β68 [E12] Leu→Phe) contains two defects in the same β chain: a β6 Glu-to-Val substitution that causes sickle cell anemia (see Chapter 20) and a β68 amino acid substitution that alters electrophoretic mobility and reduces O_2 affinity, probably by destabilizing the oxygenated conformation through steric effects introduced into helix E.[449] The affected patient, who was heterozygous for the mutant allele, exhibited symptoms of sickle cell anemia that were precipitated by infection or airplane travel. Thus an amino acid substitution that reduces O_2 affinity exacerbates the effects of a sickling mutation in the same globin chain.

Hemoglobin Variants that Modulate the Sickle Cell Anemia Phenotype

Several Hb variants modulate the severity of sickle cell anemia when co-inherited with HbS (see Table 19-8, see also Chapter 20). For example, γ globin inhibits polymerization of HbS.[450] This effect is attributable to differences in several amino acid residues compared with the corresponding β chain, including γ80 and γ87.[450-452] HbD Ibadan (β87 [F3] Thr→Lys), which introduces a lysine residue at the β87 position, is presumed to have decreased interaction with the mutant Val residue at HbS β6.[450,453] Thus HbD Ibadan inhibits HbS polymerization. Hb Korle-Bu (β73 [E17] Asp→Asn) was initially identified in an asymptomatic individual through its altered electrophoretic mobility.[454-456] The variant HbC Harlem is a double mutant that harbors the Hb Korle-Bu mutation and HbS on the same β chain.[457] Interestingly, purified HbC Harlem forms polymers less readily than HbS, suggesting that the Hb Korle-Bu mutation (β73 [E17] Asp→Asn) inhibits sickling.[457-459] Further biochemical studies showed that this mutation interferes with lateral contacts between HbS fibers by inhibiting abnormal interactions created by the β6 Val mutation of HbS.[460,461]

In contrast, Hb Quebec-Chori (β87 [F3] Thr→Ile) was identified in a compound heterozygous patient with mild to moderately severe sickle cell anemia.[462] The introduction of an isoleucine at β87 causes Hb Quebec-Chori to promote deoxygenated HbS polymerization.

CONCLUSION

The extent and level of sophistication to which normal Hb and its variants are understood is truly remarkable. Studies of these molecules over more than 50 years have elucidated paradigms related to protein and gene structure, allosteric regulation, heme/iron chemistry and the genetic basis of inherited disease. More than 1000 Hb variants are identified.[12,13] With the exception of HbS and HbC, Hb variants are rare individually, although relatively common collectively. These variants alter Hb function and structure in interesting ways, causing clinical manifestations that include cyanosis, erythrocytosis, and hemolytic anemia. Associated morbidities range from severe to minimal, although they tend toward the latter. However, symptoms caused by Hb variants, particularly cyanosis and polycythemia, are often mistaken for more common and serious disorders. Recognizing Hb variants in these circumstances can provide reassurance to patients and spare them from potential complications associated with unnecessary diagnostic procedures and therapies. Of equal importance, identification and characterization of new Hb variants continues to occur, illustrating new features of erythrocyte biology, structural insights to guide the design of Hb-based blood substitutes, and general biochemical principles that lead to improved understanding of many medically relevant proteins.

ACKNOWLEDGEMENTS

We thank Dr. Samuel Lux for helpful discussions, comments on the manuscript, and the images presented in Figures 19-17, *A* and *B*. Hemoglobin C Disease ($\alpha_2\beta_2^{6\text{ Lys}}$, $\alpha_2\beta_2^{6\text{ Lys}}$)

The first report of sickle cell anemia (SCA) in the medical literature described a dental student from Grenada, Walter Clement Noel. It was by Herrick and Irons in 1910 and introduced the word *sickle* in the title of the case report.[1] Sydenstricked described the first cases in children, recognized the association with hemolytic anemia, and introduced the term *crisis* to describe periodic acute episodes of pain.[2] The pathologic basis as a disorder of hemoglobin (Hb) was defined in 1927,[3] confirmed 2 decades later by electrophoresis that separated sickle Hb from normal Hb.[4] Neel[5] defined the genetics of the disorder and clearly distinguished sickle cell trait—the heterozygous condition (AS)—from SCA, the homozygous state (SS).

Further understanding of the molecular basis of the disorder was made possible by the finding that normal human Hb is composed of two pairs of globin subunits. Beyond the embryonic period, one globin pair is invariant (α chain), and the other pair is variable (γ, δ, or β chain). The amino acid substitution in sickle cell Hb is now known to be valine for glutamic acid in the number 6 position of the β chain (β^S). Figure 20-1 provides an overview of pathophysiology of β^S mutation).

In this chapter, *sickle cell disease (SCD)* refers to the broad group of disorders that feature erythrocyte sickling under physiologic conditions. SCD genotypes include homozygous HbSS and compound heterozygous conditions including HbS β^0-thalassemia, HbS β^+-thalassemia, and HbSC disease. HbSS, the most prevalent genotype, and HbS β^0-thalassemia are clinically similar and therefore are commonly referred to as *SCA*; these genotypes are associated with the most severe clinical manifestations. Persons with sickle cell trait (HbAS), the carrier state, rarely have clinical problems and are not considered to have a form of SCD.

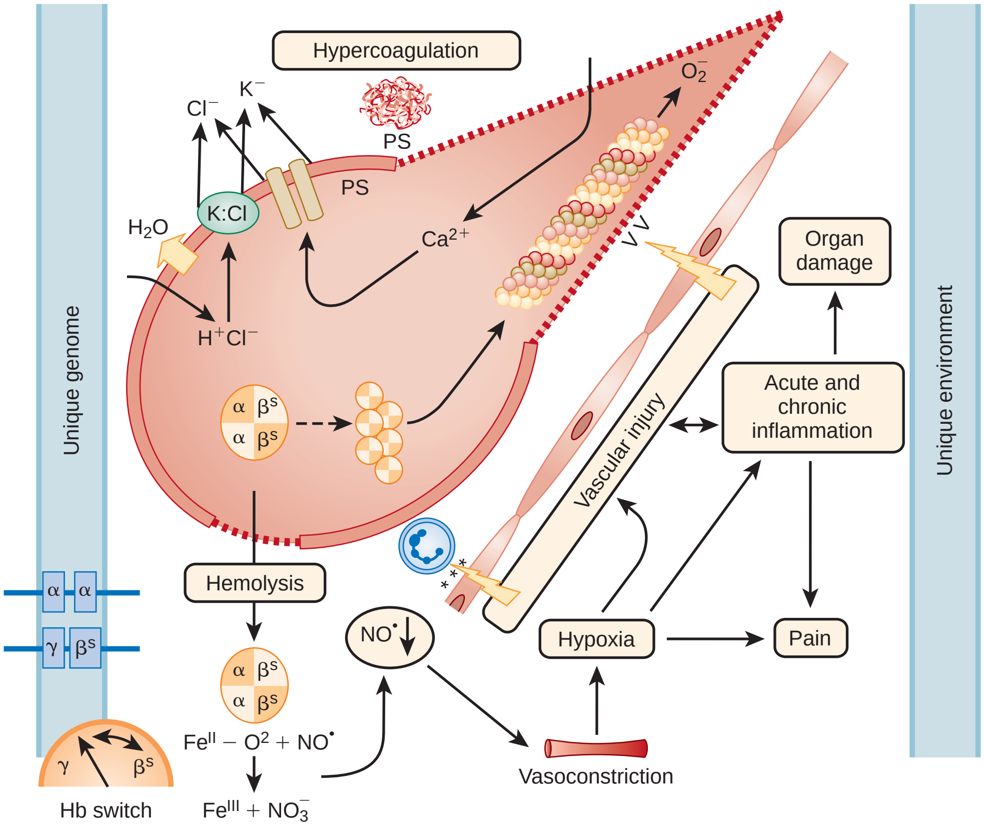

Figure 20-1 The pathophysiology of sickle cell disease. The β^S mutation results in an abnormal β globin with valine substitution for glutamic acid at the sixth position. The hydrophobic valine is exposed when the HbS tetramer assumes the deoxygenated confirmation, leading to polymerization of HbS tetramers and increased red cell deformation/rigidity. The instability of the HbS polymer leads to oxidative damage (O_2^-) of the red cell membrane. Damaged red cell membrane exposes phosphatidyl serine (PS) on the outer surface of the cell, which activates the coagulation system and leads to activation of coagulation. Membrane damage also leads to increased Ca^{2+} influx that activates the Gardos channel, leading to K^+ and Cl^- efflux. To compensate for the K^+ and Cl^- loss, water leaves the cell and it becomes more acidic/dehydrated. Acidosis activates the K^+,Cl^- cotransporter, leading to further efflux of K^+ and Cl^- and more dehydration and intracellular acidosis. Some intravascular hemolysis caused by red cell membrane damage leads to free Hb in the plasma that consumes nitric oxide (NO). Depletion of plasma NO leads to vascular endothelial dysfunction and vasoconstriction, which along with increased red blood cell (RBC) rigidity and increased adherence of sickle RBC to activated vascular endothelium leads to decreased blood flow, hypoxia, and further damage to the endothelial cells. Endothelial damage *(lightning bolts)* leads to expression of adherent proteins on the surface of the endothelial cells *(∗∗∗, VV)*, thus increasing adherence of white blood cells and RBCs to the vessel wall. Hypoxia and reperfusion leads to acute and chronic inflammation vascular injury and ultimately results in organ damage. Each patient has a unique environment (e.g., exposure to infections), and unique genetic makeup (e.g., fetal Hb expression) influences the disease phenotype, thereby making the clinical severity extremely variable.

PATHOPHYSIOLOGY

Hemoglobin S Mutation

The sickle gene mutation is common in sub-Saharan Africa and other parts of the world with endemic malaria. The allele frequency of the β^S mutation closely tracks the distribution of malaria worldwide.[6] Persistence and expansion of such a presumably deleterious mutation is explained by the benefits conferred in the heterozygous state; persons with SCT have a survival advantage from malaria.[7]

Polymorphisms that flank the β^S mutation indicate that this mutation developed independently and spontaneously at least five times.[8,9] Within sub-Saharan Africa, there are four major sickle haplotypes, each associated with a particular geographic region: Senegal, Benin, Central African Republic (CAR), and Cameroon.[10] Among North American patients of African heritage with sickle cell, 50% to 70% of chromosomes are Benin, 15% to 30% are Bantu-CAR, and 5% to 15% are Senegal.[11,12] Benin and Senegal haplotypes are associated with higher levels of fetal Hb (HbF) and fewer dense cells compared with CAR, but most African Americans are compound heterozygotes. As a result, these haplotypes have only limited predictive value for overall clinical severity, with CAR being the most severe and the Senegal variety being the least severe.[13]

A different haplotype is found in India and eastern parts of Saudi Arabia and is known as the Arab-Indian haplotype. Patients from these regions have long been recognized as having milder disease, particularly in childhood, with elevated levels of HbF.[14,15] However these patients develop chronic organ damage that may reflect, in part, their higher Hb concentrations.

Heterozygotes with HbS, HbC, HbE, α- and β-thalassemia and glucose-6-phosphate deficiency (G6PD), particularly infants, are partially protected from cerebral falciparum malaria relative to the normal population.[16]

The mechanistic basis for this survival advantage from the sickle gene is not fully understood, but as recently reviewed, the effect is multifactorial with impaired parasite growth and development, enhanced clearance of infected cells from the circulation, and altered adherence of damaged erythrocytes to the capillary endothelium.[17]

The Hemoglobin S Polymer

Polymer Structure

In 1927, Hahn and Gillespie showed that red blood cell (RBC) sickling, the change from a biconcave disk to the sickle form, was dependent on deoxygenation.[3] Harris subsequently demonstrated that cellular sickling was associated with the formation of "tactoids" of HbS that appeared as the Hb became deoxygenated.[18] Electron micrographs of sickled red cells reveal long, thin bundles of HbS fibers that run parallel to the long axis of the cell.[19,20] The ultrastructure of HbS fibers, as detailed by electron microscopy and image reconstruction, reveal a complex solid-core structure 21 nm in diameter composed of 14 filaments arranged as seven pairs of double filaments.[21,22]

The detailed crystal structure suggested by Wishner and Love and colleagues[23,24] identified several critical intermolecular contact sites. Contacts along the axis of the filament are made by α and β chains, whereas lateral contacts between filaments of a pair are largely between β chains and contacts between filament pairs are largely through α chains. Within each Hb tetramer one abnormal β chain contributes the β^S mutation, whereas the other contributes a critical receptor region around the Phe β85 residue. In this critical receptor region lie residues where mutants affect fiber formation: β73 (Korle Bu), β66 (I Toulouse), β83 (Pyrgos), and β87 (D Ibadan). Within the acceptor pocket the mutant valine closely contacts four different hydrophobic residues (β70, β73, β84, and β85). In addition to the hydrophobic interaction, water molecules that form hydrophilic interactions in the lateral contact region are present near the mutant valine.[25]

Polymer Formation

The polymerization of deoxygenated HbS (deoxy-HbS) is a highly complex process that results in the formation of gelled, aggregated HbS tetramers in equilibrium with Hb tetramers in solution. Perturbations in oxygen levels,[26] temperature,[27] pH,[28] ionic strength,[29] 2,3-diphosphoglycerate (2,3-DPG),[30] and carbon monoxide affect the formation of HbS gels. This intracellular polymerization of HbS is the sine qua non of the disorder and leads to distorted cell morphology, altered blood viscosity, circulatory sludging with occlusion of blood flow, and ultimately tissue damage and organ infarction that cause clinical manifestations of SCD.

The kinetics of HbS polymerization can be explained by a double nucleation mechanism.[31] Gelation is initiated by a process called *homogeneous nucleation,* in which single deoxy-HbS molecules aggregate. Aggregation of a few molecules is thermodynamically unstable, but once a certain number of molecules aggregate, a condition termed the *critical nucleus,* addition of further molecules produces a more stable aggregate or polymer. Thus homogeneous nucleation is highly dependent on the concentration of deoxy-HbS molecules. Gelation continues with heterogeneous nucleation that occurs on the surface of preexisting polymer. The same intermolecular contacts between the mutant valine and its receptor on the surface of the polymer are responsible for heterogeneous nucleation and cross-linking between strands.[32] While polymerization progresses, more surface area becomes available and therefore the reaction becomes autocatalytic.

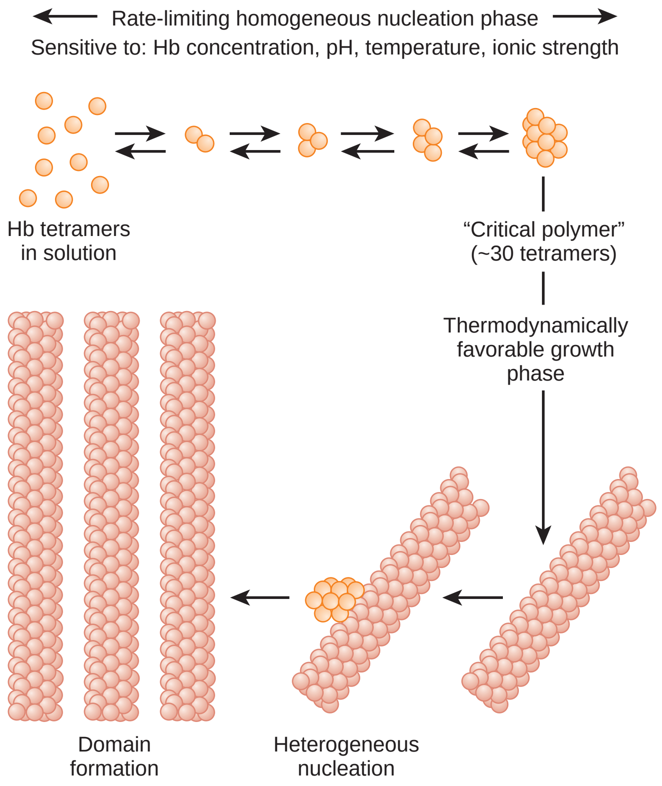
The result of this double nucleation mechanism is a measurable delay time between the initiation of polymerization and the exponential rise in polymer formation. In solution, the delay time varies as the thirtieth power of the Hb concentration: $1/t_d = K\ (C/C_s)^n$ where t_d = delay time, C = Hb concentration, C_s = Hb solubility, and $n = 30$ (the number of Hb tetramers in the critical polymer). Because n is so large, very small changes in Hb concentration have a profound effect on the delay time. This phenomenon of delayed gelling of HbS in solution is also observed in erythrocytes containing HbS.[33] The distribution of observed delay times within intact RBCs is consistent with the distribution of the mean corpuscular Hb concentration (MCHC). Slow deoxygenation causes large aligned polymers, which results in significant distortion of cell morphology.[34]

A kinetic model of HbS gelation that incorporates the concept of a critical delay time led Eaton and co-workers to propose that polymerization kinetics play an important role in the pathophysiology of SCA (Fig. 20-2).[35] Erythrocytes exposed to oxygen within the lungs are quickly "degelled" so the arterial circulation contains little polymerized HbS and few sickled cells. But as the cells enter the capillary circulation, the oxygen saturation (SpO_2) decreases rapidly and the HbS solubility also drops. If the transit time within the capillary (analogous to the delay time) is longer than 1 second, the cell will sickle and likely occlude the capillary, whereas a fast transit time means sickling will not take place in the capillary and obstruction will not occur. Patients who become hypoxic, acidotic, dehydrated, and febrile are likely to experience vaso-occlusive episodes caused in part by a shorter delay time. The hypertonic renal medulla and the acidotic, high-hematocrit environment of the spleen make these organs prime targets for sickling.

Relatively little is known about the uniformity of the depolymerization process within erythrocytes, but failure to fully melt the polymer within the lungs may lead to residual polymer.[36-38] Important variables that affect HbS polymer formation (HbF, 2,3-DPG levels, SpO_2, and pH) are heterogeneously distributed among erythrocytes, and these factors (along with membrane abnormalities and red endothelial interactions) likely play a role in the variable clinical severity of SCD.

Interactions of Hemoglobin S with Hemoglobin A and Hemoglobin F

The study of the interaction between HbS and other Hbs supports a rational basis for understanding the clinical manifestations of various sickle syndromes and provides a rationale for therapy. Investigators have extensively studied mixtures of HbS with HbF or HbA to determine



Rate-limiting homogeneous nucleation phase
Sensitive to: Hb concentration, pH, temperature, ionic strength
Hb tetramers in solution
"Critical polymer" (~30 tetramers)
Thermodynamically favorable growth phase
Domain formation
Heterogeneous nucleation

Figure 20-2 Model for the polymerization and alignment of deoxy HbS. *Hb,* Hemoglobin. *(Modified from Hofrichter J, Ross PD, Eaton WA: Super saturation in sickle cell hemoglobin solutions.* Proc Natl Acad Sci U S A *73:3035–3039, 1976; and Ferrone FA, Hofrichter J, Eaton WA: Kinetics of sickle hemoglobin polymerization. II. A double nucleation mechanism.* J Mol Biol *183:611–631, 1985.)*

the effects on gelation[39,40] and solubility.[41] The kinetic data show that both HbA and HbF have a profound, dose-related effect, increasing the delay time and decreasing HbS polymer content within erythrocytes (Fig. 20-3), but the effects of HbF are greater than HbA. Compared with pure HbS solutions, mixtures with 15% to 30% HbA (as found in HbS β^+-thalassemia) have delay times that are up to 100 times longer; mixtures with 20% to 30% HbF (as found in HbS–hereditary persistence of fetal hemoglobin [HPFH]) have delay times that are up to 10^4 times longer, and mixtures with 60% HbA (as found in sickle trait) have delay times that are 10^6 times longer.[39] HbA and HbF also increase the solubility of HbS, with HbF again being more effective than HbA. Very little if any HbF is incorporated into the polymer, suggesting that asymmetric hybrids of HbS and HbF ($\alpha_2\beta^S\gamma$) are not incorporated into polymer under most physiologic conditions,[41] whereas asymmetric hybrids of HbS and HbA ($\alpha_2\beta^S\beta^A$) are readily incorporated into the HbS polymer.

Effects on the Erythrocyte Membrane

The basic pathophysiology of SCA is directly related to HbS polymerization. However effects of polymerization on the erythrocyte membrane, which is in direct contact with this intracellular process, alter the pathophysiology of the disease. For example when the damaged membrane breaks, then intravascular hemolysis will ensue. When the altered membrane interacts with other circulating blood cells, soluble plasma factors, the vascular endothelium, and the reticuloendothelial system (RES), a wide range of additional events can lead to the highly variable but often severe phenotypic expression.

Mechanisms of Membrane Damage

In normal erythrocytes, HbA binds to the membrane around band 3 protein[42,43] and also to phospholipids on the inner surface of the membrane.[44] Hb at physiologic concentrations also stabilizes the configuration of spectrin heterodimers.[45] HbS binds to membranes more readily than HbA[46] and membrane-associated sickle Hb is a major determinant of erythrocyte rigidity.[47] Membrane rigidity has been associated with a small amount of high–molecular-weight spectrin-Hb complex in the membrane.[48]

HbS readily denatures[49] and forms small aggregates, so-called *micro-Heinz bodies* that attach with high

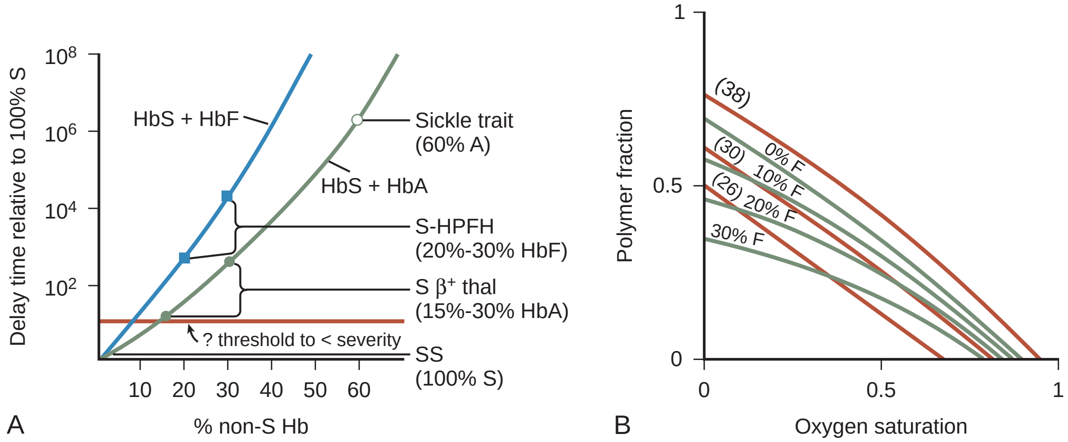


Figure 20-3 **A**, Effect of increase in concentrations of HbF and HbA on delay time of polymerization of HbS. HbS polymer formation. **B**, HbS polymer formation as a function of Spo$_2$ for different levels of HbF and for different concentrations of pure HbS at concentrations of 26, 30, and 38 g/dL. *S-HPFH,* HbS and hereditary persistence of HbF; *thal,* thalassemia. *(**A**, From Sunshine HR, Hofrichter J, Eaton WA: Requirement for therapeutic inhibition for sickle hemoglobin gelation.* Nature *275:238–240, 1978.* ***B****, From Noguchi DT, Torchia DA, Schechter AN: Intracellular polymerization of sickle hemoglobin: effects of cell heterogeneity.* J Clin Invest *72:846–852, 1983.)*

affinity to the cytoplasmic portion of band 3 protein at the HbA binding site.[50] Both band 3 protein and glycophorin are clustered above these micro-Heinz bodies,[51] and clustering of band 3 protein is associated with the deposition of specific IgG antibodies onto the cell,[50,52] which are linked to normal cell senescence and may contribute to shorten the circulating half-life of HbS erythrocytes.[53] Ankyrin is also abnormally clustered around the denatured HbS, and like band 3 protein, may be damaged in the process.[51]

Membrane damage also occurs when HbS autooxidizes to form methemoglobin (met-Hb), thereby generating superoxide and losing heme.[54] Intracellular iron from different compartments (e.g., denatured Hb, free heme, hemichromes, and nonheme iron) can bind to the inner membrane and serves as a catalyst for production of highly reactive hydroxyl radicals that cause oxidative damage to the membrane.[55] Erythrocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity was recently identified as a source of reactive oxygen species (ROS) that contribute to erythrocyte rigidity and fragility in SCA.[56] Therapies directed toward ROS may therefore be beneficial in SCA by reducing oxidative stress.[57]

Membrane Deformability

While sickle erythrocytes become deoxygenated and fill with polymerized HbS they become less deformable.[58,59] The viscoelastic properties of sickled erythrocytes can be measured by ektacytometry, which allows investigation of the deformability of HbSS erythrocytes in aggregate and has shown that decreased deformability is directly related to the amount of intracellular Hb concentration.[60] Using micropipette techniques to measure membrane deformability of individual cells, two studies have shown that the mean corpuscular hemoglobin concentration (MCHC) is the major contributor to cell rigidity, although cellular dehydration independently increases membrane rigidity.[61,62]

Cell rigidity with lack of deformability is further evidence that a structural membrane lesion is present. Most erythrocytes undergo repeated HbS polymerization/depolymerization that leads to repeated shape change from the characteristic sickled form to the normal biconcave disc, and thus represent reversibly sickled cells (RSCs). However some erythrocytes retain the sickled conformation even upon reoxygenation; the cytoskeleton of such irreversibly sickled cells (ISCs) has a variety of abnormalities including aberrant cross linking of actin,[63] dissociation of spectrin tetramers,[64] and clustering of band 3 protein and glycophorin.[65] Disordered mobility of the cytoskeleton relative to the overlying membrane may affect protein–protein interactions including binding of normal spectrin to sickle ankyrin.[66] With proteomic techniques four groups of proteins are increased in sickle erythrocyte membranes: actin accessory proteins, components of lipid rafts, scavengers of oxygen radicals, and protein repair participants.[67] All of these observations support the hypothesis that membrane rigidity is the result of cytoskeletal damage associated with HbS polymer formation and oxidative damage.

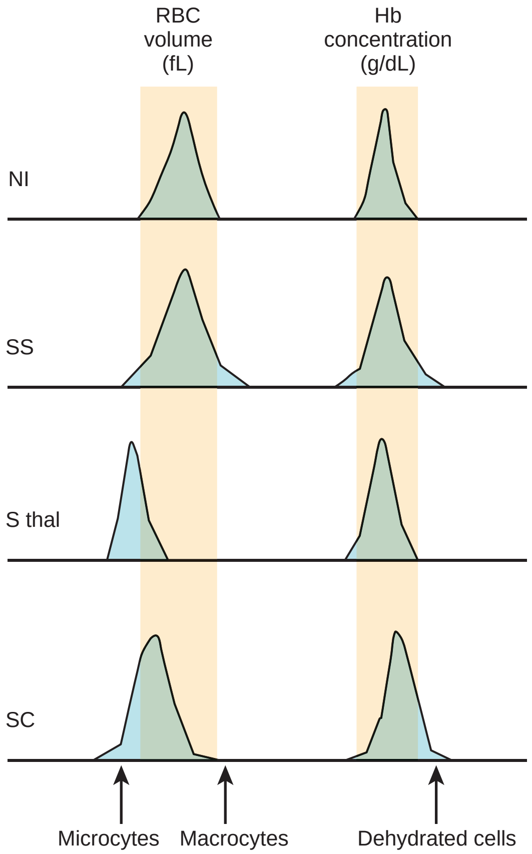

Figure 20-4 Typical distribution patterns of corpuscular volume and Hb concentration in different sickle syndromes. Note that in HbSS disease, the cells fall below and above both the volume and concentration normal *(shaded)* range. The large (microcytic) cells are the low-density reticulocytes. The dehydrated population is enriched in ISCs and low HbF. In HbS β-thalassemia syndromes, the entire volume curve is shifted toward the left, and few dense cells are seen. In HbSC disease, the microcytes are often spherocytic, very dehydrated cells. *Hb*, Hemoglobin; *Nl*, normal; *RBC*, red blood cell; *SC*, HbSC disease; *SS*, HbSS disease; *S thal*, HbS β thalassemia.

Hemoglobin Concentration

Patients with SCA have a wide variation in their erythrocyte density, including many light cells (reticulocytes) and more dense cells (MCHC >37 g/dL) than normal erythrocytes. This is reflected in the histograms of mean corpuscular volume (MCV) and Hb from the sickle genotypes (Fig. 20-4). Sickle erythrocytes separated by density (and therefore MCHC) obstruct flow in an artificially perfused capillary system in proportion to their intracellular Hb concentration.[68] However there appears to be no correlation between the percentage of dense cells and the frequency or onset of vaso-occlusive events.[69] A newly described in vitro system with microfluidics and endothelialized channels[70] may represent an improved method to study the rheological characteristics of sickled erythrocytes and will aid the investigation of pathologic consequences of ISC and dense cells as they interact with vascular endothelium.

The heterogeneity of red-cell shape and density in SCA is influenced significantly by the distribution of HbF within the erythrocytes. For unexplained reasons, HbF is not evenly distributed among erythrocytes (both in normal persons and patients with SCA) and defines a subpopulation known as F cells.[71] Because HbF helps prevent HbS polymerization, F cells sickle less often and thus survive longer in the circulation.[72] The densest cell fraction in SCA contains the oldest erythrocytes that contain the lowest amounts of HbF and include the ISC fraction.[73]

Erythrocyte Shape Changes

RSCs have normal shape and normal viscosity when oxygenated. The vaso-occlusive complications of SCD may be because of the fact that these cells are able to circulate into the microvasculature because of their normal rheologic properties when oxygenated but then become distorted and more viscous as they become deoxygenated within the small capillaries. In contrast ISCs are slender, elongated cells with blunt ends that are visible even on an oxygenated peripheral blood smear (Fig. 20-5). These cells are extremely dense with MCHC of greater than 44 g/dL, have little HbF to dilute their concentrated HbS, and survive in the circulation for only a few days.[73] ISCs can be formed in vitro by prolonged deoxygenation[74] and by repeated oxygenation–deoxygenation cycles. Reversible oxidative damage to β-actin and loss of ubiquitination of α-spectrin leads to formation of an ISC membrane skeleton that is "locked" because it cannot disassemble or reassemble.[75] Antioxidants can reduce the formation of ISCs in vitro.[76] ISC numbers vary widely from patient to patient and have been correlated with hemolysis and splenomegaly[77] but only poorly with vaso-occlusive severity.

Ion Transport and Cell Volume

Abnormal cation permeability of the sickle erythrocyte is characterized by calcium loading, potassium depletion, acidosis, and dehydration, all of which enhances the tendency for HbS polymerization (see Fig. 20-1). HbS polymer formation upon deoxygenation causes a reversible potassium loss and sodium gain in the cell.[78] Abnormal water and cation movements across the cell membrane have been associated with a variety of pumps, channels, and leaks involving potassium (K^+), sodium (Na+), chloride (Cl^-), calcium (Ca^{2+}), and magnesium (Mg^{2+}). Although the pathogenesis of these pathways remains

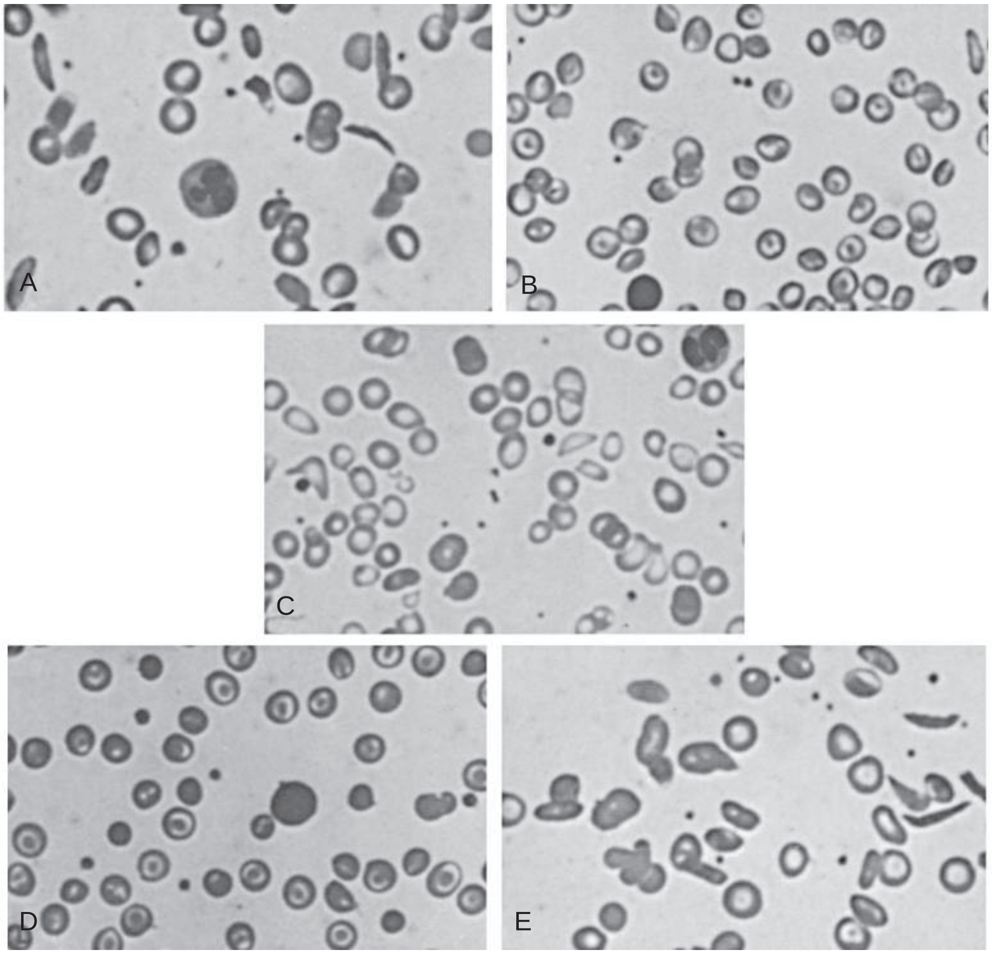

Figure 20-5 Oxygenated peripheral blood smears from individuals with SCD (**A**), HbSC disease (**B**), HbS β^0 thalassemia (**C**), homozygous HbC disease (**D**), and HbSD disease (**E**).

incompletely understood, they are undoubtedly related to the physical distortion associated with sickling,[61,62,78-85] oxidant damage,[86] and the Hb mutation itself.[87]

At least two major erythrocyte membrane channels are responsible for cellular dehydration: the calcium-activated potassium-selective process (Gardos channel, encoded by the *KCNN4* gene) and the K^+Cl^- cotransporter (encoded by *KCC* with multiple isoforms). These channels are critical for cation flux and water regulation in the sickle erythrocytes, and thus influence Hb concentration and cell volume. Sickle reticulocytes exposed to deoxygenation and HbS polymerization accumulate sufficient Ca^{2+} to activate the Gardos channel,[88] which results in osmotic-driven water loss and rapid RBC dehydration to a much greater extent than with other transporters. The Gardos channel can be inhibited by the antimycotic agent clotrimazole, and a short-term study demonstrated benefits on cellular hydration.[89] A novel Gardos channel inhibitor (senicapoc, ICA-17043) entered into formal clinical trials, and although having substantial effects on cellular hydration,[90] a definitive phase III double-blinded placebo-controlled trial demonstrated no efficacy for reducing vaso-occlusive events.[91]

A second pathway involved in RBC dehydration is the potassium chloride channel (KCC). The KCC is active in reticulocytes as part of normal volume reduction during cellular maturation but has increased activity in sickle reticulocytes with deleterious consequences. The KCC pathway is stimulated to lose K^+, Cl^-, and water when predominantly young sickle erythrocytes are exposed to a low pH environment, as occurs in areas of poor perfusion.[92] The KCC pathway is also activated by deoxygentation of Hb[76,93]and by low levels of Mg^{2+}.[94] Genes for four KCC isoforms have been identified; *KCC1*, *3*, and *4* isoforms are present in normal and sickle erythrocytes, but the latter may have N-terminal splicing variants of these isoforms.[95] The KCC pathway can be inhibited by magnesium in vivo,[94] and Mg^{2+} is depleted in sickle erythrocytes possibly through an abnormal Na–Mg exchange.[96] Preliminary studies demonstrated the effectiveness of oral magnesium in the prevention of cellular dehydration,[97] and a pilot trial suggested utility for intravenous (IV) magnesium in the setting of acute vaso-occlusive pain.[98]

External Membrane Interactions

Increased Erythrocyte Adhesion to the Endothelium

In 1979 investigators first discovered that sickle erythrocytes have an abnormal propensity to adhere to vascular endothelial cells with an adhesive force that results from numerous attachment sites that withstand detaching forces found in low shear vascular beds.[99-101] While cells flow through vessels of critical dimension, abnormal flow caused by endothelial interactions increases the odds that polymerization and obstruction will occur (see Fig. 20-1). Support for this hypothesis comes from studies that suggest a correlation between adhesiveness and clinical severity.[102]

A variety of surface adhesion molecules on sickle erythrocytes are involved in this abnormal endothelial interaction. Sickle reticulocytes are especially prone to adhesion, having recently exited the marrow (where adhesion is required during erythroid maturation) and without any splenic filtrative circulation to allow “grooming” of the sticky young erythrocytes. Sickle erythrocytes bind to both the endothelial cells and to subendothelial extracellular matrix proteins such as laminin, thrombospondin, and fibronectin, which can become exposed after adhesion. Sickled cells have the highest affinity for laminin because of two isoforms of the protein that bear the Lutheran blood group antigens (B-CAM and LU).[103,104] Adhesion proteins to thrombospondin on reticulocytes include CD47 and VLA-4 ($\alpha_4\beta_1$ integrin, which also bind to VCAM-1), whereas CD44 is the adhesion protein that binds to fibronectin.

Endothelial cells have different surface molecules depending on their location. For example, CD36 is expressed on microvascular but not large-vessel endothelium.[105] Endothelial cells also express differing amounts of surface molecules and become more or less adherent depending on environmental stimuli. Cytokines such as interleukin-18 and tumor necrosis factor[106] promote endothelial adherence, largely because of up-regulated VCAM-1 expression. In the setting of infection and inflammation, endothelial cells also modify their adhesion molecule profile.

Circulating endothelial cells can be identified in patients with SCA, and they exhibit an activated phenotype including surface expression of ICAM-1, VCAM-1, E-selectin, P-selectin, and tissue factor.[107] Increased production of endothelial derived adhesion molecules (VCAM-1, ICAM-1, and E-selectin) was observed in 10 adult patients during acute SC pain crises.[108] Soluble levels of VCAM-1, ICAM-1, and E-selectin were elevated and independently associated with organ damage, pulmonary hypertension (PHT), and mortality.[109]

Membrane Lipid Orientation and Coagulation Defects

Normally phospholipids of the erythrocyte membrane are partitioned with amino phospholipids such as phosphatidylserine (PS) and phosphatidylethanolamine (PE) located on the inner cytoplasmic surface, whereas sphingomyelin and phosphatidyl choline (PC) are exposed on the outer surface (see Fig. 20-1). This asymmetry is not unique to the red cell and probably reflects a general structural pattern that keeps the amino phospholipids from activating soluble coagulation factors. In RSC, PS and PE flip back and forth from the inner leaflet to the outer leaflet during oxygenation and deoxygenation. Exposure of PS or PE on the outer surface during sickling may lead to increased phagocytosis by PS-binding proteins secreted by macrophages[110] and may bind to specific PS receptors on endothelial cells.[111] Alteration of the fatty acyl groups in PC results in changes in cell shape and deformability in SS cells, suggesting that the species composition of PC can affect membrane permeability and cellular deformability.[112]

Abnormal lipid asymmetry accelerates clotting in vitro, and PS-positive sickle erythrocytes are correlated with markers of thrombin generation (prothrombin fragment F1.2, thrombin–antithrombin complexes) and fibrin degradation (D-dimers and plasmin–antiplasmin complex).[113]

Other markers of thrombophilia observed in patients with SCA are reduction in proteins C and S,[114] platelet activation, and microparticles from endothelial cells, platelets, monocytes, and red cells that promote coagulation and may increase during crises.[115]

Procoagulant and anticoagulant proteins as well as platelets play an important role in sickle erythrocyte adhesion to the endothelium. With sickle erythrocytes already having increased adhesiveness, the additional effects of increased levels of von Willebrand factor,[116] activated platelets,[117] and thrombospondin[118,119] further increase RBC adhesiveness and make SCA a legitimate hypercoagulable state. Investigation with anticoagulants and antiplatelet agents are just now beginning, and may have a role in the prevention or amelioration of vaso-occlusive events.

Hemolysis and Nitric Oxide Depletion

The erythrocyte life span is shortened in SCA to approximately 10 to 20 days. The premature destruction of sickle erythrocytes includes both extravascular clearance by the RES (two thirds contribution) and intravascular processes (one third contribution). Extravascular hemolysis is enhanced by externalized PS exposure on the erythrocytes, which is recognized by macrophages with PS-specific receptors.[110] The membrane changes found on sickle erythrocytes are similar to those seen in nucleated cells undergoing apoptosis (externalization of PS, annexin binding to and blebbing of the membrane, and cell shrinkage). Intravascular hemolysis is probably occurring at a steady-state (with 4 μM of plasma Hb)[120] but with exacerbations caused by infectious or immunologic etiologies that lead to the concept of hyperhemolysis. In this setting, the massive release of Hb into the plasma overwhelms the normal binding and clearance mechanisms of haptoglobin and hemopexin and may lead to pathologic outcomes.

Nitric oxide (NO) is a critically important molecule that regulates vascular tone and functions as a cell-signaling molecule. NO is produced by a specific synthetase found in endothelial cells (endothelial nitric oxide synthase [eNOS]) that use L-arginine in an NADPH-dependent enzymatic reaction. NO increases intracellular cyclic guanosine monophosphate (GMP), which decreases smooth-muscle calcium concentrations, leading to muscle relaxation, vasodilation, and increased regional blood flow. NO also suppresses platelet aggregation, secretion of procoagulants, and reduces expression of endothelial cell adhesion molecules.[121] Patients with SCA have elevated levels of plasma-free Hb, which consumes NO with resulting functional consequences of an "NO-depletion" state.[122,123] Intravascular hemolysis has been postulated to cause a wide variety of clinical events in patients with SCA such as PHT, priapism, leg ulcers, stroke, and renal insufficiency,[124,125] although the validity of this hypothesis has been recently called into question.[126,127] Newer evidence suggests that an entirely different pathway may lead to PHT, one that involves marrow hyperplasia and high levels of circulating placental growth factor, which leads to endothelin-1 release and pulmonary vasoconstriction.[128]

Acute and Chronic Inflammation

The HbS mutation and the pathophysiology of repeated sickling with erythrocyte–endothelium interactions leads to an acute and chronic inflammatory state with widespread endothelial dysfunction and vasculopathy. Markers of inflammation include increased levels of leukocytes, neutrophils, platelets, C-reactive protein (CRP), von Willebrand factor, and fibrinogen, all increased at steady state and during crises.[129,130] Increased adhesion of sickle erythrocytes, reticulocytes, neutrophils, and platelets to vascular endothelium can initiate local inflammatory responses that alter the expression of endothelial surface molecules and lead to release of soluble forms into the plasma. Hypoxia, increased proinflammatory cytokines, and infections can activate vascular endothelium and leukocytes, which in turn can further increase adhesion molecules on both circulating cell surfaces and on endothelial cell surfaces[130] (see Fig. 20-1). Over time, the endothelium becomes damaged enough that a chronic vasculopathy develops, causing clinical complications even without any acute sickling or vaso-occlusive events.

Circulating leukocytes and in particular neutrophils are also involved in the pathophysiology of SCA. Baseline white blood cell (WBC) and neutrophil counts in patients with SCA are elevated in the steady state, usually to twice the normal value. The degree of elevated WBCs is directly related to early mortality[131] and increased acute chest syndrome (ACS)[132] and has been suggested as a predictor of clinical severity in affected infants.[133] Activated neutrophils are common in the steady state and also during vaso-occlusive crises, and they have enhanced adhesion to endothelium during vaso-occlusive events.[134] In a transgenic sickle mouse model, neutrophils are involved in reperfusion inflammation after hypoxia, but the process is abrogated by blocking adherence with an antibody to P-selectin,[135] which has led to therapeutic efforts in humans that target the selectins as a means to reduce vaso-occlusive pain. E-selectin has been identified as a crucial portal for invasive pneumococcal disease in a mouse model of SCA, and its down modulation by hydroxyurea can prevent fatal infection.[136]

Recently two additional inflammatory pathways have been identified that have relevance for the pathophysiology and clinical manifestations of SCD. The first is the invariant natural killer T-lymphocyte (iNKT) cell, which when activated can mediate pulmonary inflammation and has been associated with the development of ACS.[137] The adenosine A2A receptor (A2AR) agonist regadenoson reduces iNKT-cell activation and can decrease inflammation in sickle cell mice,[138] and this agent is currently in human clinical trials. The second pathway is through mast cell activation, which promotes neurogenic inflammation and nociceptor activation in a murine model; specific inhibition with imatinib reduced hyperalgesia and suggests that pharmacologic manipulation of mast cells may influence inflammation and vaso-occlusive pain.[139] General reduction of inflammation using statins may improve endothelial function as well. A pilot study demonstrated that simvastatin was safe, well-tolerated, and had benefits on markers of inflammation suggesting a potential therapeutic role.[140]

Genetic Modifiers

In some ways SCA can be considered a simple disease, at least from the standpoint of pathogenesis, because the precise genetic mutation is known, the selection pressure for the origin and propagation of the sickle mutation is understood, the genetics of inheritance and transmission are straightforward, and the expression of the abnormal β^S allele is predictable and deleterious. Despite this designation as a simple monogenic disorder, however, SCA is highly complex because of its phenotypic variability. Patients have a wide range of laboratory findings, clinical disease expression, and severity outcome that presumably reflect additional genetic and environmental influences.

Given the clarity of the pathogenetic basis for SCA, it is surprising how difficult the search for genetic modifiers of SCA has been. Perhaps because of differences in the definition or measurement of certain phenotypes, or because there are additional confounders, the identification of genetic modifiers for common laboratory and clinical events in SCA has been mostly fruitless, with a few notable exceptions. Even common mutations that originated in Africa with the same survival advantage against malaria do not have a predictable effect. For example G6PD deficiency is a common single-gene variant that also protects against malaria. In the United States, the prevalence of the A variant is about 10% to 13% among males, and there is no increased incidence of G6PD deficiency in SCD.[141] Within the Cooperative Study of Sickle Cell Disease (CSSCD), the presence of G6PD deficiency in 801 males was not associated with more hemolysis or increased anemic episodes.[142] Presumably no effects were observed because this mild variant of G6PD deficiency typically becomes manifest only in older erythrocytes, and the erythrocyte lifespan observed in SCA is very short. More recently G6PD deficiency has been associated with a risk of cerebral vasculopathy among children with SCA,[143] although this association has not been verified by other investigators.

α-Thalassemia trait is another common finding among patients with SCA, with a prevalence of 30% to 40% in the United States and exceeding 50% in some parts of the world. The most common form of α-thalassemia trait is caused by a 3.7-kb deletion involving the entire α_2 gene.[144] Additional deletional and nondeletional forms of α-thalassemia are found but are not as common. The primary effect of concomitant α-thalassemia is to limit the supply of α globins and thus further favor the competition of nonsickle β globin (γ globin) in the intracellular struggle for available α globins.[145,146] This lowers the intracellular HbS content and thus prolongs the delay time for HbS polymerization. The resulting erythrocytes are more deformable because they have higher membrane area to volume ration; hence they have less potassium loss and cellular dehydration and a lower MCHC.[147] Patients with SCA and α-thalassemia tend to have smaller, lighter cells with a higher circulating Hb concentration and lower rate of hemolysis.[147,148] Indeed α-thalassemia trait combined with SCA has been associated with a lower risk of cerebral vasculopathy and stroke, a finding recently confirmed in a large cohort of children with SCA.[149] However this combination does not necessarily translate into a better clinical outcome, because α-thalassemia has been associated with more vaso-occlusive pain,[150] renal infarction, and avascular necrosis (AVN) of the femoral head.[151] This may be the result of increased hematocrit and concomitant increase in viscosity in certain organs.

The baseline HbF levels in patients with SCA are highly variable, ranging from very low values (<5%) to very high values (>30%). Because HbF is known to ameliorate the phenotypic expression by reducing HbS polymerization, the origin of this marked variability has been of great interest. In the CSSCD any increment of HbF above 4% was associated with reduced painful events,[152] and HbF levels greater than 8.6% were associated with decreased mortality.[131]

Three broad categories of genetic mutations have been described that increase HbF postnatally. The first category includes large deletions of the γδβ-globin gene locus region on chromosome 11, which are rare but result either in δβ-thalassemia or pancellular hereditary persistence of fetal Hb (HPFH) as described in Chapter 21. Patients who inherit HbS on one allele and a large pancellular HPFH deletion on the other have a condition that does not sickle under physiologic conditions. Patients with HbS/HPFH represent a unique syndrome with 20% to 35% HbF levels overall and distributed in all red cells, which results in normal Hb concentration, mild microcytosis, no sickled erythrocytes on the peripheral blood smear, and no clinical disease manifestations.[153]

A second category of mutations that increase HbF in patients with SCA is linked to the β-globin gene region but does not feature large deletions of the gene locus and so has historically been termed *nondeletional HPFH*.[154,155] HbF is usually distributed heterogeneously in these disorders, but because the fraction of F cells has a tight but nonlinear association with the %HbF,[156] some of these patients approach a pancellular distribution. Despite the linkage to the β^S mutation, a search within the promoter region of the γ-globin genes typically does not identify any specific mutations.[157] The only nondeletional mutation clearly associated with an increased %HbF is the −158C to T polymorphism (rs7482644, also called the *XmnI polymorphism* because of the creation of a restriction enzyme cutting site) found in the $^G\gamma$ promoter, which is found in the Senegal and Arab-Indian (Saudi) β-globin haplotypes.[14,15] These haplotypes are found commonly in genetic isolates in Western Africa, in Shiite Saudi Arabians, and in the Orissa region of India.[158,159] Among patients in the United States with SCA, fewer than 10% have one chromosome with either of these haplotypes and fewer than 2% are homozygous for the Senegal haplotype.[11,12]

The third category of genetic mutations that influence HbF levels in patients with SCA are those not linked to the β-globin region. Some patients have HbF levels ranging from very low (<3%) to much higher levels (15% to 20%); the latter are sometimes referred to as patients with HbSS/high HbF to distinguish them from HPFH variants. Many nonglobin genetic loci regulating HbF have been postulated and pursued including an elusive X-linked locus,[160] but discovery of the *BCL11A* gene as a potent regulator of %HbF levels has vindicated this pursuit and provides mechanistic insights into HbF regulation and even therapeutic opportunities for patients with thalassemia and SCA. The BCL11A locus on chromosome 2p15 was first identified as a modifier of HbF levels using genome wide-association studies[161,162] and subsequently this locus has been shown to have the greatest genetic influence on baseline HbF levels identified to date. The BCL11A protein is now recognized as a major biologic repressor of γ-globin gene expression,[163] and silencing its expression can yield "de-repression" with high HbF levels and correction of the sickle phenotype in a murine model.[164] In humans at least four single nucleotide polymorphisms affect *BCL11A* expression and thus HbF levels.

An additional gene locus regulating HbF levels on chromosome 6 has been pinpointed to the intergenic region of *HBS1L-MYB* at 6q23.[165] Several noncoding polymorphisms within this region have been associated with higher HbF levels, but to date, no specific mechanisms have been elucidated for this genetic locus, although changes in *MYB* expression seem to be important.[166] It is important to note that all genetic modifiers of HbF have not been identified; together, genetic variants within the *BCL11A*, *HBS1L-MYB*, and β-globin loci account for only 30% of the phenotypic variability of endogenous HbF expression and 50% of the heritable variability.[167] Additional genetic regulators of HbF will be identified, but their effects will likely be smaller and their prevalence will be much lower.

Additional genetic modifiers that influence specific clinical phenotypes have long been sought for patients with SCA, including stroke, pain, ACS, leg ulcers, nephropathy, and AVN, among others. It is likely that networks of genes that respond to or modulate hemolysis, vasoregulation, inflammation, cell adhesion, hemostasis, and oxidative stress play roles in these phenotypes (see Fig. 20-1). Unfortunately most of these efforts have been hampered by the lack of accurate and rigorous phenotypes, small sample sizes, high false-discovery rates, and absence of validation cohorts. Moreover studies that investigate candidate genes are inherently limited to those genes, so unknown genes or networks can only be identified using unbiased "agnostic" approaches. Finally discovering an association between a genetic variant and a phenotype does not necessarily mean causality, and functional studies are needed to confirm the biologic significance and effect of any specific genetic association. The importance of a validation cohort is illustrated by the report that 90% of previously published genetic polymorphisms associated with stroke were not associated with stroke in a new cohort of children with documented stroke phenotype.[149] At this time few genetic variants have been found that reliably influence any specific phenotype in patients with SCA except the UGT1A1 promoter polymorphism,[168] which is also potent in the normal population for bilirubin levels. With improved gene-sequencing techniques including whole exome analysis, it is likely that new genetic variants will be identified that influence clinical phenotypes and even treatment responses to hydroxyurea.[169]

DIAGNOSIS

Fetus

The ability to perform prenatal diagnosis for SCD has progressed significantly since 1978 when Kan and Dozy[170] described the DNA polymorphisms around the β-globin gene that were in linkage disequilibrium with the β^S gene. Techniques for identification of the A-to-T substitution in codon 6 responsible for the glutamic acid-to-valine change in β globin have evolved from the use of restriction enzymes and homologous synthetic oligonucleotides to polymerase chain reaction–based amplification of DNA and sequencing.[171-174] Sufficient DNA can be obtained from a small number of fetal cells obtained by amniocentesis or as early as 8 to 10 weeks' gestation by chorionic villous biopsy.[175] The desire to avoid the small risk of fetal loss associated with these invasive techniques has led to investigation of noninvasive prenatal diagnosis by testing fetal cells or free fetal DNA known to circulate in the plasma of pregnant women.[176] Preimplantation genetic diagnosis (PGD) is now an established reproductive alternative to prenatal diagnosis in many specialized centers. Single-cell polymerase-chain reaction diagnosis of blastomeres followed by selection of unaffected embryos for standard in vitro fertilization has led to the birth of unaffected twins to a couple both with sickle trait.[177] PGD has been used to facilitate selection of an unaffected histocompatible sibling donor for hematopoietic stem-cell transplantation of SCD.[178]

Newborns

The newborn with SCD is generally not anemic or symptomatic until toward the end of the first year of life because of the protective effects of fetal Hb. Screening combined with comprehensive follow-up care was first begun by Pearson in New Haven and Serjeant in Jamaica in the 1970s.[179,180] Because recognition of the disease in a newborn can lead to prevention of mortality and morbidity, the National Institutes of Health (NIH) recommends that all infants be screened in the neonatal period for SCD,[181] and as of 2007 all 50 states and the District of Columbia perform universal screening for SCD.[182] The method used for initial screening varies from state to state with most using isoelectric focusing (IEF) or high-performance liquid chromatography (HPLC) as their primary screening method. These tests can be performed on cord blood or on dried blood specimen blotted on filter paper. False negative screens using these methods have been reported in infants who received perinatal transfusions before screening.[183] Diagnosis can also be performed using polymerase-chain reaction amplification of deoxyribonucleic acid (DNA) extracted from filter paper.[184] Universal screening compared with targeted screening of newborns of parents at risk has been shown to identify more infants with disease, prevent more deaths; and is cost effective in areas where sickle trait is present in 7 to 15 of 1000 births.[185,186] Considerations of logistics and equity have contributed to the decision for

universal screening in the United States and the United Kingdom.[187]

Older Children

After the first few months of life, as β^S-globin production increases and HbF declines, the clinical syndrome of SCD emerges (Table 20-1). Although at 1 week of age the Hb level of infants with HbSS is statistically lower than that of normal HbAA infants, the overlap between the two groups is considerable and does not diverge much before the second month of life.[179] Anemia and reticulocytosis is usually evident by 4 months of age.[179] ISCs are often absent from the peripheral blood of young children, and the morphology is typical of that of normal newborns: target cells, fragments, and poikilocytes. By 3 years of age, the typical peripheral blood smear is seen, including ISCs, target cells, spherocytes, fragments, biconcave disks, Howell-Jolly bodies, and nucleated red cells. The amount of HbF decreases with age, as in normal children, but this occurs much more slowly.[179,188]

CLINICAL MANIFESTATIONS

The clinical manifestations of SCD are extremely variable. Some patients are entirely asymptomatic, whereas others suffer often from acute painful episodes. Most patients fall between these extremes and have relatively long asymptomatic periods punctuated by occasional clinical crises. The complex nature of the clinical variability from patient to patient and over time in each

patient has been prospectively studied on a large scale in the CSSCD, under the auspices of the Sickle Cell Disease Branch of the National Heart, Lung, and Blood Institute (NHLBI).[189,190]

Acute Sickle Cell Crises

The term *sickle cell crisis* was defined by Diggs[191] as "any new syndrome that develops rapidly in patients with SCD as a result of the inherited abnormality." There are three categories of sickle crisis: vaso-occlusive, sequestration, and aplastic, and they are covered individually in the next few sections. The best perspective on how these acute events play out in a typical group of children comes from a report by Gill and colleagues describing the experience of almost 700 infants studied for 10 years as part of the CSSCD.[192] The age at first event is displayed in Figure 20-6.

Vaso-occlusive crises are acute, often painful episodes resulting from intravascular sickling and tissue infarction. In a prospective study of children with HbSS disease studied since birth in Jamaica, painful crisis was the first symptom in more than one fourth of the patients and the most common symptom after the age of 2 years.[193] Vaso-occlusive crises (also called *vaso-occlusive episodes* or *events*) are the major clinical manifestations of SCD and occur most commonly in the bones, soft tissues, lungs, liver, spleen, brain, and penis. Sometimes the differential diagnosis is difficult, because there is no definitive objective hallmark of vaso-occlusive crises and they can mimic other pathophysiology.

Acute Painful Crisis

The most common acute vaso-occlusive crisis is pain. Virtually all patients with HbSS disease experience some degree of acute pain. For many these episodes are mild and managed entirely at home, school, or work. Little is known about the extent or nature of pain-coping activities that go on outside the medical setting, but diary studies suggest that they are numerous. The "tip" of the pain "iceberg" is made of those episodes that drive patients to seek medical attention. These episodes vary widely among patients[152] (Fig. 20-7) and represent the most common reason for patients to visit outpatient offices and emergency departments and be admitted for inpatient care. Despite the fact that there is variation in how or why individual patients decide to seek attention for a given episode of pain, epidemiologic evidence strongly indicates that patients with higher rates of medical attention for pain have lower levels of fetal Hb, higher WBC counts, higher steady-state Hbs, and higher

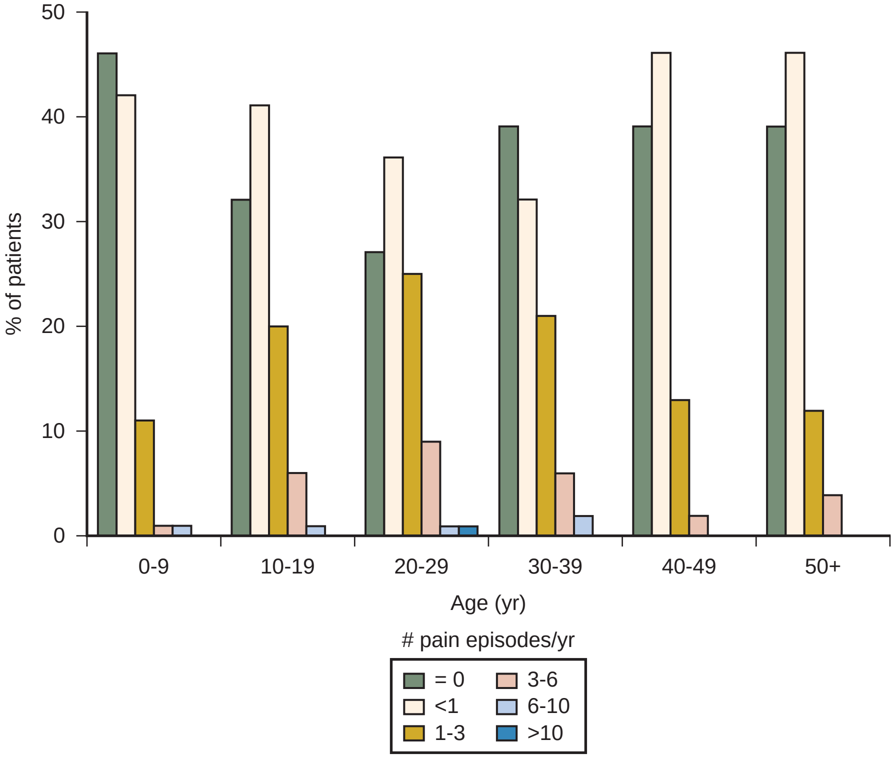

Figure 20-7 Distribution of pain rate among patients with HbSS disease. *(Data from Platt OS, Thorington BD, Brambilla DJ et al: Pain in sickle cell disease: rates and risk factors.* N Engl J Med *325:11–16, 1991.)*

mortality.[131,152] Some studies have suggested that infections, changes in climate,[194,195] and psychological factors[196] may precipitate pain episodes, although commonly no precipitating factors can be identified.

Patients typically experience rapid onset of deep, gnawing, throbbing pain, usually without any abnormal physical or laboratory findings but sometimes accompanied by local tenderness, erythema, warmth, and swelling. The underlying pathology is bone marrow ischemia, sometimes leading to frank infarction with acute inflammatory infiltrate.[197-199] The most commonly involved areas are the lumbosacral spine, knee, shoulder, elbow, and femur. Less often, the sternum, ribs, clavicles, calcaneus, iliac crest, mandible, zygoma, and mandible are involved.[200] Sympathetic joint effusions during acute periarticular episodes are particularly common in the knees and elbows. Typically joint aspiration yields straw-colored fluid, usually with a "noninflammatory" profile. Rarely sterile purulent exudates are found.[201] Given the range of marrow involvement and inflammatory response, it is not surprising that the findings in patients with the most inflammation mimic the findings of osteomyelitis, and those without such findings are at risk of being considered malingerers.

Even in patients with measurable signs of inflammation, the diagnosis of infarction is favored over osteomyelitis. The results of one study suggest that acute long-bone infarction is at least 50 times more common than osteomyelitis.[202] In this study of 41 acute long-bone infarcts, 38% affected the humerus, 23% affected the tibia, and 19% affected the femur. All patients experienced local tenderness, with swelling in 85%, joint findings in 68%, and local heat in 65%. Fourteen percent appeared "toxic," 21% had a temperature greater than 39°C, and 43% had a temperature lower than 38°C. The total WBC count ranged between 7200 and 43,000 cells/mm^3, with a mean leukocytosis of 17,000 cells/mm^3. The mean sedimentation rate was 30.5 mm/h, with a range of 3 to 66 mm/h. Although various radionuclide scans have been suggested to distinguish between infarction and infection,[203-207] in many studies such investigations were inconclusive.[208-210] Magnetic resonance imaging (MRI) of patients with HbSS disease shows decreased intensity of short relaxation time/echo-time pulse-sequence imaging, owing to hyperplastic marrow that converts to high intensity on long relaxation time/echo time images in painful crises,[199] but no definitive series compares infarction to infection. Therefore despite the progress made in the development and use of imaging techniques, a definitive diagnosis of osteomyelitis in SCD still relies more upon clinical assessment together with positive cultures from blood or bone obtained by aspiration or biopsy than upon any single imaging modality.[211]

Except for a positive blood or tissue culture, no laboratory test can differentiate acute infection from painful crisis.[198,212] Needle aspiration and culture of the highly suspicious area is critical for isolating the organism and should be considered before initiating empirical antibiotic therapy. The aspirated fluid may be quite purulent even in the patients with sterile infarcts. In most series, the most common organism causing osteomyelitis is *Salmonella*[213] though *Staphylococcus*, *S. pneumoniae* and Gram-negative enteric bacilli are also common.[214] Initial empiric antibiotic therapy should be chosen to cover these possibilities. Treatment failures are seen when anything but the most aggressive antibiotic regimens are used.

As described earlier, episodes of acute bone pain and impressive signs of inflammation may be difficult to distinguish at outset from osteomyelitis. More common and just as challenging is the evaluation and management of severely painful episodes in patients without obvious signs of inflammation. Some of these patients show laboratory evidence of acute inflammation such as elevated CRP,[215] fibrinolysis such as elevated D-dimers,[216,217] or red-cell trapping such as loss of dense cells.[218] These measurements are not helpful in the management of individual cases, and should not be used as an attempt to "validate" an individual patient's report of symptoms. In a research setting, however, these measurements done on large numbers of patients with and without symptoms provide clues to potential innovative therapeutic interventions. For example the common finding of elevated acute-phase reactants stimulated a trial of methylprednisolone for treating acute bone pain.[219] This preliminary work showed that a short course of high-dose corticosteroid decreased the duration of severe pain; however, it resulted in more "rebound" attacks after treatment was discontinued. Similarly despite the fact that previous trials of aspirin therapy were not encouraging,[220] there is significant interest in the role of platelets,[221,222] soluble procoagulants,[223] anticoagulants,[224,225] and endothelial cells[135] in the precipitation or propagation of vasoocclusion and has reopened these as potential lines of treatment.[226-228]

In children younger than 5 years of age, the small bones of the hands and feet are often affected, even to the distal phalanges, and in contrast to most episodes of bone pain in older children, physical findings are common. This painful dactylitis ("hand-foot syndrome") is typically the first clinical manifestation of SCD. The young child cries with pain; refuses to bear weight; and has puffy, tender, and warm feet, hands, or both. The child may appear acutely ill, be febrile, and have an impressive leukocytosis. At the onset of soft-tissue swelling, there are usually no bony changes on radiographs. After 1 to 2 weeks, subperiosteal new bone, irregular areas of radiolucency, cortical thinning, or complete destruction of bones can be seen. All the bone changes are usually reversible but may persist for as long as 8 months.[229,230] A rare complication, permanent shortening of the digits after hand-foot crisis, has been reported.[231] Dactylitis before age 1 year is a strong predictor of overall severity (stroke, death, high pain rate, or recurrent ACS) by 10 years of age,[133] although recent single-institution evidence suggests dactylitis is not a strong predictor of subsequent pain or ACS.[232] In addition to dactylitis the risk for severe disease is further increased if the child has also experienced an episode in which the Hb dropped below 7 g/dL, and/or the baseline WBC count was elevated.[133]

Acute Chest Syndrome

ACS is an acute illness of lung injury characterized by chest pain, fever, and/or respiratory symptoms, accompanied by a new pulmonary infiltrate on chest radiograph. The diagnostic criteria most commonly include radiographic evidence of a new segmental pulmonary infiltrate and one or more of the following: fever, tachypnea, cough, or new-onset hypoxia; increased work of breathing (intercostal retractions, nasal flaring, accessory muscle use); or chest pain.[233] The term *acute chest syndrome* was introduced by Charache et al[234] and reflects the difficulty of establishing a definitive etiology and emphasizes the fact that in individual patients, knowing the specific etiology is less critical for management than being able to assess the magnitude and pace of the lung injury.

The critical pathophysiology is that only deoxygenated HbS polymerizes and that reoxygenation eradicates the polymer. The lung is the critical organ that protects the arterial side of the circulation from the sludge of sickle polymers. When the lung is injured, underventilated, or inflamed such that a ventilation/perfusion (V/Q) mismatch exists, this protection is inadequate, and downstream tissues including the injured lung itself become increasingly susceptible to sickling and ischemia. In fact, when the flow is eventually restored in a sickle mouse model, reperfusion injury occurs with activation of iNKT cells[137] and p-selectin–inhibitable movement of inflammatory cells into the tissue.[135]

Although some patients, particularly adults, initially can provide a full-blown picture of chest pain, hypoxia, and abnormal x-ray findings, the diagnosis of ACS in young patients can be difficult to make. Often the diagnosis becomes clear only days into an event that started as a fever without source or pain. Children younger than 4 years of age often have few signs at presentation: in one study, 35% to 40% had a normal lung examination; 30% to 40% had no tachypnea; and 30% to 50% had no tachycardia.[235] The radiographic evolution often lags behind the clinical progression. In one series, only 36% of patients had an abnormal x-ray on presentation, although all eventually developed abnormal radiographic findings.[236]

Vichinsky and associates demonstrated that almost half of all patients who developed ACS were initially admitted for other reasons, often with vasoocclusive pain.[233] Opioid analgesics and pain of the spine, ribs, and abdomen can lead to hypoventilation with decreased tidal volume, development of atelectasis, and V/Q mismatch. The subsequent regional hypoxemia results in further intrapulmonary sickling. Secretory phospholipase A2 (sPLA2) and serum CRP have been proposed as possible laboratory predictors of ACS development but not widely adopted.[237-239] Elevated sPLA2 as a trigger for simple transfusion appeared to reduce the risk of developing ACS compared with standard therapy in one small uncontrolled trial,[240] but a larger multicenter feasibility trial was challenged by poor enrollment.[241]

ACS is a leading cause of morbidity and mortality in SCD.[131,242] It represents the second most common acute complication (pain episode is first) with a rate of 12.8

cases per 100 patient-years[132] and the most common condition at the time of death.[131,233] The highest incidence is in children aged 2 to 4 years (25.3 per 100 patient-years in SCA), and lowest in adults (8.8 per 100 patient-years in SCA).[132] Patients who have not experienced an episode of ACS have a longer life expectancy than those who have, and those with a higher level of HbF and lower steady-state WBCs have a lower attack rate for ACS.[132] Induction of fetal Hb with hydroxyurea therapy lowers incidence of ACS in all age groups.[243,244]

Asthma or reactive airways may represent a distinct or overlapping comorbid condition[245] and appears to be a risk factor for vaso-occlusion and for ACS.[246-248] Patients with SCD and asthma were two to four times more likely to develop ACS than those without asthma, had longer hospital stays, and experienced a higher incidence of painful episodes.[249,250] Analysis of the CSSCD cohort revealed that comorbid asthma is a significant risk factor for mortality for patients with SCD[251] and should be treated aggressively.[252]

Vichinsky and colleagues prospectively studied 671 episodes of ACS.[233,253] The most common etiologies were fat/bone-marrow embolus, and bacterial, atypical bacterial (*Chlamydia, Mycoplasma*), viral, or mixed infection. In contrast to patients with infection, those with bone-marrow embolus were more likely to have an associated episode of bone pain, chest pain, abnormal neurologic symptoms, and fall in platelet count.[253] Regardless of etiology ACS is always accompanied by some degree of localized sickling and lung ischemia. There is considerable change in blood counts at the time of presentation in patients with ACS. The Hb concentration drops an average of 0.7 g/dL that likely reflects sludging and intrapulmonary sickling, and WBC counts increase an average of 69%. The mean partial pressure of oxygen (pO_2) was 71 mm Hg with one fifth of the patients having a pO_2 less than 60 mm Hg. Transcutaneous SpO_2 measurements may not be reliable in SCD, and most clinical transcutaneous pulse oximeters overestimate the fractional arterial oxygenated (oxy-)Hb saturation.[254,255] It is unwise, therefore, to place too much reliance on single SpO_2 measurement in isolation.

Several important therapeutic principles emerged from the Vichinsky study.[233,235] First, bronchodilator therapy was remarkably effective in patients with wheezing or pulmonary function tests indicating obstruction. This is consistent with the observation that measurable airway hyperactivity exists in many children with HbSS even without a history of asthma.[256] Second, red-cell transfusion improved oxygenation. Simple transfusion is as effective as exchange transfusion and may indicate that rapid reversal of intrapulmonary sickling is therapeutic. Third, the prominence of *Chlamydia* and *Mycoplasma* underscores the importance of including macrolide antibiotics in the initial broad empiric therapy.

All patients with ACS must be managed in the hospital setting with frequent and close monitoring. Broad spectrum antibiotics (including a macrolide), bronchodilator therapy, frequent incentive spirometry, and simple transfusion represent the mainstay of early intervention. Oxygen therapy should be provided for patients with hypoxia, and exchange transfusion is indicated for worsening hypoxia or clinical deterioration despite simple transfusion. Chest and rib pain often lead to splinting and atelectasis that may exacerbate or even precipitate ACS; therefore analgesic therapy should not be withheld but should be titrated to analgesic effect with careful monitoring and frequent reevaluation. Fluid overload with pulmonary edema/effusion and congestive heart failure can occur, so careful attention to fluid balance is critical. For patients with poor respiratory effort or rising oxygen requirements, the use of noninvasive ventilation such as continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) may be useful.[257,258] Progression to respiratory failure is not uncommon, and if the patient is ventilated, bronchoscopy may have both diagnostic and therapeutic benefit. Detection of plastic bronchitis and removal of branching bronchial casts can improve hypoxemia and V/Q mismatch.[259,260] Although most patients with ACS recover uneventfully, the course is unpredictable and can progress to rapid, unexpected deterioration that leads to multiorgan failure and death.

Acute Abdominal Pain

Severe acute abdominal pain is a common presentation that can pose a difficult differential diagnosis. The etiology of abdominal pain in children with SCD is often benign (e.g., secondary to constipation or gastroenteritis) but can reflect mesenteric sickling and vertebral disease with nerve root compression. A true sickle-related abdominal crisis can be accompanied by guarding, tenderness, rebound, fever, and leukocytosis that is indistinguishable from an acute surgical abdomen. Often the patient is the best judge and can state whether the pain is characteristic of a sickle "crisis."

These patients should receive general supportive measures with the omission of high-dose opioid analgesics until the clinical trajectory becomes clear. Patients with severe pain should be given nothing by mouth and followed closely by both medical and surgical personnel. Abdominal films, including upright views, may be helpful in identifying retained stool, air-fluid levels consistent with infection-related hypomotility, or even a perforated viscus. Usually the patient with vaso-occlusive pain remains stable or improves slightly with hydration and mild sedation. In extreme cases in which the clinical situation is deteriorating, emergency surgical exploration may be necessary. Simple or exchange transfusion should be done before surgery if possible.

Acute focal right upper quadrant pain may be a result of acute cholecystitis or intrahepatic sickling.[261,262] Abdominal ultrasonography will indentify cholelithiasis and choledocholithiasis in the hands of a skilled operator. The presence of gallstones and a clinical syndrome characteristic of cholecystitis is common but does not always mean that the symptoms are the result of the stones. However most gallstones in young patients with SCD are symptomatic, and patients benefit from elective cholecystectomy. Patients with acute cholecystitis should have surgery only after the gallbladder has had a chance to "cool down," because perioperative management of emergent surgery can be fraught with complications.[263]

(For further discussion see the Hepatobiliary System section).

On rare occasions there may be intrahepatic sickling and even hepatic sequestration. Intrahepatic sickling can result in acute right upper quadrant pain from acute sickle hepatic crisis, hepatic sequestration, and/or SCD intrahepatic cholestasis. Acute hepatic crisis commonly presents with acute right upper quadrant pain, tender hepatomegaly, nausea, low-grade fever, and jaundice.[262] Transaminases are rarely greater than 300 IU/L and serum bilirubin levels are usually less than 15 mg/dL.[262,264] The crisis usually resolves within 2 weeks with IV hydration and analgesia. Hepatic sequestration also presents with sudden tender hepatomegaly, but in contrast presents with an acute anemia and without cholestasis or transaminitis.[265,266] Treatment is to replace circulating volume with crystalloid or simple transfusion. Transfusion must be undertaken judiciously, because the liver may "release" the endogenous sickle erythrocytes leading to elevated hematocrit consequent problems secondary to hyperviscosity. Exchange transfusion should be considered. SCD intrahepatic cholestasis is a syndrome of right upper quadrant pain, nausea/vomiting, fever, tender hepatomegaly, leukocytosis, and extreme direct hyperbilirubinemia. There is a broad spectrum of severity in intrahepatic cholestasis that can include acute liver failure with bleeding diathesis, encephalopathy, renal failure, and progression to multiorgan failure and is associated with high mortality, particularly in adults.[267-269] These hepatic complications are not to be confused with the "benign hyperbilirubinema" described by Buchanan et al[261] and is characterized by marked conjugated hyperbilirubinemia, only mild transaminitis, and no liver synthetic dysfunction. This entity resolves spontaneously within 2 to 8 weeks and may represent a very mild variant of intrahepatic cholestasis.

Acute Central Nervous System Event

Acute infarction of the brain can result in a devastating stroke, which occurred in approximately 7% to 10% of children with SCA in the era before transcranial Doppler (TCD) screening.[270,271] The incidence is estimated to be 0.7% per year during the first 20 years of life, with the highest rates in children 5 to 10 years of age.[272] Stroke may occur as an isolated event but also appears in the setting of evolving ACS, aplastic crisis with severe anemia, viral illness, painful crisis, priapism, or dehydration.[270,271] The most common underlying lesion is an intracranial arterial stenosis or obstruction, usually in the distal internal carotid, the proximal middle cerebral, or the anterior cerebral arteries.[273-275] Pathologically these vessels whose endothelium has presumably been chronically injured by sickle erythrocytes show hyperplastic intima with proliferation of fibroblasts and smooth muscle.[276] The lumen may be narrowed or completely obliterated by the vascular lesion, suggesting that acute sickling may simply be the "last straw," causing acute infarction in the setting of a chronic vasculopathy. Hemiparesis, focal seizures, gait dysfunction, and speech defects are the most common presenting signs, but persistent cognitive and psychological impairments commonly accompany motor deficits after stroke.

A careful discussion of the evaluation of the child with new neurologic symptoms is provided by Adams.[277] As soon as cerebral ischemia is suspected and the patient stabilized, the best initial diagnostic test is a noncontrast CT scan. However diagnostic imaging should never delay immediate therapeutic intervention. Although CT may not be positive for infarction within the first 6 hours of ischemia, it can rule out hemorrhage or nonischemic etiologies. MRI with diffusion-weighted imaging (DWI) and fluid-attenuated inversion recovery (FLAIR) sequences are highly sensitive and provide better detail of the areas of ischemia within minutes of ischemia and remain abnormal for several days.[278,279,280] The typical findings are infarcts associated with major vessel obstruction or distal obstruction of smaller vessels leading to infarction in the "border zone" area between the anterior cerebral and middle cerebral vessels.[281,282] Assessment of the intracranial and cervical artery vasculature using three-dimensional time-of-flight (TOF) magnetic resonance angiography (MRA) is becoming increasingly useful in the early evaluation of the patient with new symptoms[283] and is nearly as accurate as conventional cerebral angiography.[284]

Patients with suspected acute neurologic deficits should immediately receive IV hydration while blood is being cross-matched, because signs and symptoms of stroke can often be quickly reversed, even with isotonic IV fluids. Simple transfusion to a Hb target of approximately 10 g/dL is also helpful to alleviate acute intracranial sickling and can be accomplished in most clinical settings. In a tertiary hospital the standard approach to treating a patient with acute infarction is immediate exchange transfusion (see "Transfusion" for details). There are no data for the use of recombinant tissue plasminogen activator (tPA) in sickle-associated cerebral ischemia for either children or young adults.

Patients treated with simple or exchange transfusion usually show marked improvement in motor function, although the prognosis is considerably worse for those with multiple infarcts. After the initial transfusions, a chronic maintenance transfusion program with a goal of suppressing HbS to less than 30% reduces the incidence of stroke recurrence to 10% to 15%, representing a substantial reduction in stroke rate compared to no intervention.[274,285-289] Patients whose initial stroke was temporally unrelated to another medical event (e.g., ACS) may be at higher risk for recurrent stroke even while receiving regular transfusions.[290] The appropriate duration of chronic erythrocyte transfusions for secondary stroke prophylaxis has not been firmly established. Two prospective studies documented a high risk of recurrent stroke (60% to 70%) after discontinuation of either a short-term (1 to 2 years) or long-term (5 to 12 years) transfusion regimen.[274,291] Therefore an indefinite transfusion program is currently recommended to prevent secondary stroke. Although clearly beneficial, indefinite maintenance transfusion carries the risks of allosensitization,[292] autoantibody formation,[293] transfusion-borne infections, and the certain progression to iron overload. Bone-marrow transplantation in patients who have had strokes can be curative,[294] although parenchymal brain disease may progress.[295]

Hydroxyurea treatment with increased HbF served as an alternative to chronic transfusion[296] for effectively preventing secondary stroke in a single institution.[297] The subsequent multicenter trial (Stroke With Transfusions Changing to Hydroxyurea study; SWiTCH) compared the efficacy of standard treatment (chronic transfusions and chelation) to alternative treatment (hydroxyurea and phlebotomy) for children with SCA, previous stroke, and iron overload.[298] SWiTCH was terminated early after a scheduled interim analysis indicated statistical futility for reaching the composite primary study endpoint of both recurrent stroke rate and improved iron burden.[299] The alternative treatment arm had an increased stroke recurrence rate compared with the standard treatment arm but within the predicted stroke margin of the study design; however, the iron unloading from serial phlebotomy was not superior to daily deferasirox, so the composite study endpoint was not reached. For the children in SWiTCH who had a recurrent stroke, risk factors included severe cerebral vasculopathy, younger age at first stroke, and history of transient ischemic attack (TIA). The duration of follow-up study may have been too short to demonstrate any differences in cerebral vasculopathy between the transfusion and hydroxyurea arms. Because of the inferior results on SWiTCH's hydroxyurea and phlebotomy arm, chronic transfusion therapy with chelation remains the mainstay of secondary stroke prevention in children with SCA.

Patients who develop severe cerebral vasculopathy (moyamoya syndrome) appear to have a high risk for recurrent stroke despite adequate chronic transfusion. One retrospective evaluation of chronic transfusions for secondary stroke prevention[300] revealed recurrent stroke was more common among patients with moyamoya (11/19 patients, 58%) than without moyamoya (7/25 patients, 28%). Given this increased risk, some advocate for surgical revascularization to restore circulation to the at-risk hemisphere. Although there are no randomized, controlled trials in children with SCA and moyamoya disease to determine the effectiveness of indirect surgical revascularization procedures such as encephaloduroarteriosynangiosis (EDAS)[301] or pial synangiosis,[302] postsurgical angiography has shown promising revascularization of the affected area.

Given the devastating consequences of overt clinical stroke and the difficulties in preventing recurrent stroke, application of radiologic techniques for noninvasive assessment of the brain and its vasculature has focused attention on two areas: identifying children at high risk for primary stroke by TCD ultrasonography and identifying children with asymptomatic "silent" cerebral infarcts (SCI) by MRI.

In the early 1980s the utility of TCD to measure intracranial arterial blood flow was first reported.[303] TCD allows an easy, noninvasive method of measuring cerebral blood velocity in the circle of Willis. The highest time-averaged maximum velocity (TAMV) measured in the distal internal carotid artery (ICA) and proximal middle cerebral artery (MCA) has become the standard reported TCD value. In children with SCA, TCD can identify intracranial arterial vasculopathy,[304,305] although an inverse relationship between hematocrit and TAMV values has been recognized.[306] A landmark prospective single-institution study of untreated children with SCA demonstrated that higher TCD velocities in the distal ICA or proximal MCA were associated with an elevated risk of primary ischemic stroke.[307] A subsequent study with a longer follow-up range confirmed that TCD velocities reflect a continuum of stroke risk, but 200 cm/s represents a potential threshold value, above which the risk of primary stroke is very high. For 315 untreated children with SCA studies for an average of 64 ± 24 months, 25 (8%) had TAMV greater than or equal to 200 cm/s, and 10 of these children (40%) had a primary stroke.[308]

Similar to secondary stroke prevention with chronic transfusion, positive results have also been demonstrated for primary stroke prevention in SCA for children with abnormal TCD velocity. In the multicenter prospective Stroke Prevention Trial in Sickle Cell Anemia (STOP) with 130 asymptomatic children with abnormal TCD measurements (>200 cm/s), subjects were randomized to transfusions or standard care. The study was terminated early when only 1 of 63 transfused children compared with 11 of 67 untreated children had strokes, representing a 92% decrease in the relative stroke rate in the treated group.[309] A subsequent randomized controlled trial (STOP 2) tested whether chronic transfusions for primary stroke prevention based on abnormal TCD could be safely discontinued after at least 30 months in children who had not had an overt stroke and who had reversion to low-risk TCD (<170 cm/s) with chronic transfusion therapy. After 79 of a planned 100 children were randomized, the trial was also terminated early because 16 of 41 subjects randomized to stop transfusion achieved endpoint (14 reversions to high-risk TCD without stroke and 2 ischemic strokes) versus 0 of 38 maintained on chronic transfusion treatment.[310] The current TCD with Transfusions Changing to Hydroxyurea (TWiTCH) clinical trial is testing whether hydroxyurea can be used as an alternative treatment to indefinite transfusions in the setting of abnormal TCD.

A systematic study of MRI in asymptomatic children with SCA revealed that unanticipated SCIs are associated with an increased risk of subsequent clinical stroke.[311] However in older children (mean age, 11 years) without evidence of prior central nervous system (CNS) disease, TCD and MRI results are often discordant, indicating that these tests may be measuring different aspects of CNS pathology.[312] Brain MRI has revealed that 18% to 25% of children in the CSSCD had evidence of SCI.[313-315] These silent infarcts are associated with impaired performance on psychometric tests that measure fine motor skills and cognitive ability.[316-318] Older children (>6 years) with silent infarcts were more likely to have a history of seizures, low Hb level, and high WBC count ($>11.8 \times 10^9$/L).[315] In a study of 392 children studied prospectively up to 10 years, elevated WBC count, dactylits, and low Hb (<7 g/dL) before the age of 2 years were associated with adverse outcomes including strokes.[133] In other studies low hematocrit,[319] ACS[320] and hypertension[321] have been associated with silent infarcts and/or clinical strokes. These observations suggest that MRI might be used to screen older children with poor school performance or evidence of other risk factors.

Clinical trials are underway for treatments of younger children who develop evidence on MRI of silent infarcts or abnormal intracranial Doppler flow measurements including transfusions,[322] hydroxyurea,[323,324] or bone marrow transplant.[325]

Not all acute focal neurologic events in patients with SCA are infarcts. Intracranial hemorrhage is the other major category of sickle-related neurologic event, although the incidence is higher among adults than children.[320] Hemorrhagic stroke presents as a sudden severe headache, sometimes with neck pain, vertigo, syncope, nystagmus, ptosis, meningismus, nausea/vomiting, or photophobia. Many of these episodes are subarachnoid hemorrhages from small bleeding aneurysms that probably arise from intimal damage during childhood. Multiple aneurysms with extensive collaterals (similar to moyamoya disease) are often found during angiographic evaluation of children with cerebrovascular disease. Successful aggressive neurosurgical approaches to these bleeding lesions have been published[326-328] and suggest that angiography should be done to identify patients with surgically amenable lesions.

Priapism

Priapism occurs in males of all ages, but the incidence and prevalence are not well established. In a Jamaican study of 104 males age 10 to 62 years, 42% reported at least one episode of priapism, with a median age of onset of 21 years. [329] The long-term follow-up study of patients in Los Angeles determined that approximately 7% of males with SS and about 2% of those with SC develop priapism, with a median age of onset of about 22 years.[13] A questionnaire survey administered to 98 patients below the age of 20 in Dallas found the mean age at the initial episode to be 12 years, with an average number of episodes per patient of 15.7 and an 89% actuarial probability of experiencing priapism by age 20.[330] Prolonged sexual arousal, fever, cold exposure, nocturnal tumescence (rapid eye movement [REM] sleep), full bladder, dehydration, alcohol, cocaine, and testosterone therapy have all been implicated as triggers.[331-333] Because early intervention and treatment may prevent irreversible penile fibrosis and impotence, patients and parents should be educated in advance of its occurrence to prevent embarrassment and to treat prolonged priapism as a urological emergency.

Four clinical entities are described: stuttering priapism, with short (less than 2 to 3 hours), often multiple episodes; acute prolonged priapism (more than 24 hours), which can persist for weeks; chronic priapism, a painless induration that may last for years; and acute-on-chronic priapism, acute painful episodes complicating chronic induration. Sexual dysfunction was reported by 46% of patients with a history of priapism.[329] In general young patients with brief episodes restricted to the corpora cavernosa (bicorporal priapism) are less likely to become dysfunctional,[334,335] whereas adults with involvement of the corpora cavernosa and corpus spongiosa (tricorporal priapism) tend to have prolonged episodes and higher than a 50% chance of becoming impotent.[336] Urinary retention requring catheterization may complicate such acute episodes. Patients with tricorporal involvement are also particularly susceptible to acute severe neurologic complications and overall increased morbidity, even those treated with exchange transfusion.[337,338] They should be monitored closely for early neurologic symptoms, especially headache.

Diagnostic studies such as technetium scans, MRI, Doppler flow studies, and measurements of corporal pressures, Hb electrophoresis, and blood gases have been used in a variety of settings to help define the anatomy and potential prognostic features of priapism. As yet they have not had an impact on clinical decision making in individual patients.[339-341]

A consensus on treatment of priapism has not been reached, and there are no controlled clinical trials to guide therapy.[342,343] Short episodes of acute priapism usually occur on awakening and can be managed at home. Patients should be instructed to urinate often, perform mild exercise, increase oral fluid intake, and soak in a warm tub and take analgesics. If the episode does not resolve within a few hours, the patient should receive medical treatment for a typical vaso-occlusive episode with aggressive IV fluids and analgesics. If the episode persists beyond 4 hours, intracavernosal aspiration and instillation of an α agonist should be performed and repeated.[344,345] Although the role of RBC transfusion is somewhat controversial,[346] simple red-cell transfusion may relieve priapism and provide safety for urgent surgical intervention.[334] Exchange transfusion may produce results in 6 to 8 hours,[347,348] although most do not show signs of detumescence for 24 to 48 hours, and some do not respond at all.[349] Use of intracorporal and oral α-adrenergic agents has been tried successfully in a small experimental group in Paris in both acute and chronic settings,[345] and in one group of patients with stuttering priapism in Jamaica, stilbestrol was helpful in preventing recurrences.[350] Numerous medical therapeutic options have been attempted, including diethylstilbestrol, gonadotropin-releasing hormone analogs, various adrenergic agonists, antiandrogens, baclofen, gabapentin, phosphodiesterase type 5 (PDE5) inhibitors, and hydroxyurea.[342,351,352]

Surgical shunting procedures should be reserved for patients who have not shown any signs of detumescence 12 to 24 hours after corporal irrigation and/or transfusion, particularly if they are postpubertal. Even partial responses should be considered adequate to postpone surgical intervention, since historically these procedures have carried a high complication rate with subsequent penile deformities and impotence. The most conservative shunt is the Winter procedure or one of its modifications, whereby a needle or scalpel is inserted through the glans into one of the corpora and the viscous blood is aspirated. This temporarily allows for drainage of cavernous blood into the systemic circulation and has been successfully used in patients with SCA.[353] Intermittent compression with a blood pressure cuff is critical to limit refilling. Anecdotal evidence suggests that penile implants to correct impotence may be more easily done soon after an impotence-causing episode.[354,355]

Splenic Sequestration

Along with bacterial sepsis, historically one of the leading causes of death in children with SCA is the acute splenic sequestration crisis.[356] Children with SCA who have not yet undergone autosplenectomy as well as older patients with other forms of SCD[357] may develop sudden, rapid, massive enlargement of the spleen with trapping of a considerable portion of the red-cell mass. Patients suddenly become weak, pale, and dyspneic, with rapidly distending abdomen, left-sided abdominal pain, vomiting, and hypovolemic shock. The tempo of this crisis may be so fast that the patient dies before reaching the hospital. On physical examination there may be profound pallor plus hypotension with cardiac decompensation and massive tender splenomegaly. The Hb concentration is at least 2 g/dL lower than baseline, accompanied by a brisk reticulocytosis with increased nucleated red cells (distinguishing it from the aplastic crisis described below) and moderate to severe thrombocytopenia caused by splenic trapping of platelets.[356] This complication has been described in patients as young as 8 weeks of age.[358]

Emond described the natural history of acute sequestration crisis in a cohort of 308 children with SCA in Jamaica.[359] Eighty-nine patients experienced 113 attacks, with 67 children having their first attack before the age of 2 years. There were 13 fatalities, 10 of which occurred before the age of 2. The most commonly associated clinical problem was upper respiratory tract infection and ACS. Sixteen percent of the patients had positive blood cultures. Recurrences were frequent, occurring in 49% of survivors of the first attack. A parental education program directed toward teaching parents the technique of spleen palpation and the urgency of seeking medical attention for enlarged spleen and pallor led to an increase in the incidence of cases (from 4.6 to 11.3 per 100 patient years of observation) and decreased the fatality rate (from 29.4 per 100 events to 3.1 per 100 events).

Therapy is the emergency restoration of intravascular volume and oxygen-carrying capacity by the immediate transfusion of packed red cells, even if only unmatched blood is available. Once normal cardiovascular status is restored, patients improve rapidly. The spleen usually shrinks within a few days, and the thrombocytopenia resolves. Care must be taken to not transfuse to baseline Hb, however, because with resolution the spleen releases the endogenous trapped erythrocytes and may result in a relative erythrocytosis with hyperviscosity, what is sometimes referred to as the "overshoot phenomenon" after simple transfusion. Recurrence of sequestration is common, usually within 2 to 3 months of the initial episode as the protection afforded by the transfused cells is lost. To eliminate recurrence some have recommended elective splenectomy after the first significant episode,[360] whereas others more concerned with postsplenectomy sepsis have suggested splenectomy only after two episodes of sequestration.[356] Emergent splenectomy during the acute sequestration is not indicated.

Kinney's review from Duke University of splenic sequestration strengthens the position of those who favor elective splenectomy for children who have had one episode of acute sequestration, especially if the initial event was life-threatening.[361] In this series of 23 patients, four underwent early splenectomy, seven were observed carefully, and 12 were placed on a maintenance transfusion program. Of those treated using transfusion, two were well and still receiving transfusion, three had recurrences while still on transfusion, four experienced recurrences within 3 months of the last transfusion, and only three remained well at 11 months (3.9 years after the last transfusion). Fourteen percent of children became alloimmunized, and 1 patient developed non-A, non-B hepatitis. Eventually 14 of the 23 patients underwent splenectomy. All were immunized against pneumococcus and were prescribed penicillin for prophylaxis. None had experienced a life-threatening infection 65.6 patient years later. Serjeant has demonstrated in a 22.5 year follow-up study that children in Jamaica who are postspenectomy are not at greater risks for infection than a matched control group of patients with SCA.[362]

Rao has described a subacute form of splenic sequestration in 11 patients characterized by increased spleen size, 25% drop in hematocrit, less than 100,000 platelets, and reticulocyte count elevation above patient's baseline. All responded to chronic transfusion programs, but seven patients had recurrent episodes after transfusions were stopped and eventually required splenectomy.[363]

Aplastic Crisis

The clinical characteristics of the transient aplastic crisis of SCD result from the abrupt cessation of erythropoiesis, most commonly because of acute parvovirus infection.[364-366] In the normal steady state, patients can compensate for the decreased red-cell survival (15 to 50 days) by increasing the bone marrow output six- to eightfold, with the absolute reticulocyte count sometimes reaching 400 to 500×10^9/L. Temporary cessation of bone marrow activity because of suppression by intercurrent viral or bacterial infection causes the hematocrit value to fall as much as 10% to 15% per day with no compensatory reticulocytosis. The short-lived HbF-poor cells are the first to disappear from the circulation, whereas the cells containing more HbF persist. This natural selection of HbF-containing cells accounts for the apparent increase in the percentage of HbF during aplastic episodes.

Patients usually have pallor and fatigue but are without jaundice and have laboratory evidence of severe anemia below baseline with associated severe reticulocytopenia. Spontaneous recovery is usually heralded by a markedly elevated nucleated RBC count, followed in 1 or 2 days by a brisk reticulocytosis. Spontaneous recovery usually occurs within 7 to 10 days and may require no therapy, but some patients are extremely ill at presentation and many require short-term hospitalization and erythrocyte transfusions. This recovery phase, with the characteristic anemia, nucleated red cells, reticulocytosis, and occasional hyperbilirubinemia, may be responsible for most cases referred to as hyperhemolytic crisis.

In 1981, two groups linked transient aplastic crisis to parvovirus B19 infection.[367,368] The Jamaican group subsequently documented the epidemiology and follow-up treatment of parvovirus in a cohort of infants identified

TABLE 20-2 Bacteremia and Associated Acute Events in a Cohort of 694 Children with Sickle Cell Anemia and Hemoglobin Sickle Cell Disease Monitored Prospectively from Infancy

SC, HbSC disease; *SS*, HbSS disease.

at birth: 308 with SCA and 239 controls.[369,370] They made a number of important observations: 1) the frequency of infection (about 40%) did not differ between sickle and control groups; 2) 20% of infections in the sickle group did not result in clinically recognizable aplasia; 3) 100% of aplastic episodes were associated with parvovirus; 4) no patients had recurrent aplasia; and 5) 45% of infected patients maintained an elevated parvovirus-specific IgG after 5 years. The secondary attack rate of siblings was 50% to 60%; therefore affected siblings should be monitored for evolving aplastic crisis when a child is diagnosed with an acute parvovirus B19 infection. Parvovirus B19 has also been implicated as the etiologic agent in erythema infectiosum (fifth disease),[371,372] although often the classic rash of fifth disease is absent.[372,373] Parvovirus B19 infection has also been related to several other sickle cell complications including acute splenic sequestration,[374] hepatic sequestration,[375,376] ACS,[233] glomerulonephritis,[377,378] and stroke.[379] Many patients are seropositive for parvovirus B19 without history of a known aplastic crisis, suggesting many infections are subclinical.[380] The relationship between parvovirus and erythropoiesis has been studied in detail. The virus specifically retards late erythroid precursor differentiation[381] and is responsible for temporary erythroid aplasia in a broad array of hemolytic anemias.[373]

Infection

Acute Infection

Bacterial infection is the most common cause of death in children with SCA.[382-384] In one study the risk of acquiring sepsis or meningitis was higher than 15% in children younger than 5 years, with an associated mortality of approximately 30%.[385] In young children the risk of pneumococcal sepsis appears to be 400 times that of normal children, and *Haemophilus influenzae* sepsis appears to be two to four times as common.[386] These two reports are from the period before the licensing of conjugated vaccines to *S. pneumoniae* and *H. influenzae*. In general the organisms responsible for infection are primarily encapsulated bacteria and not unusual pathogens (Table 20-2), but the infections that they cause in such patients occur more often and are more severe.

The major risk factor for this increased vulnerability to infection is splenic dysfunction. The spleen normally serves two separate immunologic functions: 1) clearance of particles from the intravascular space, and 2) antibody synthesis. Both functions are impaired in SCD.

During the first year of life, "functional asplenia" develops in patients with SCD, particularly in those with SCA.[387] This is heralded by the appearance of red cells with micronuclear remants (Howell-Jolly bodies) and intracellular vacuoles that appear as irregular surface characteristics ("pits"). When the percent of pitted red cells exceeds 3.5%, the spleen is generally considered nonfunctional.[388] Splenic dysfunction develops early in life, with 50% of 2068 children with SCA having greater than 3.5% pitted red cells by 2 years of age. Appearance of dysfunction was less rapid and less common in children with HbSC or HbS β^+-thalassemia. Despite palpable splenomegaly, children with elevated pitted RBCs have no splenic uptake of technetium-99m (^{99m}Tc) sulfur colloid and are susceptible to the most serious infectious complication of asplenia and pneumococcal sepsis.[389] Repeated infarction results in a nonpalpable, fibrotic, often calcified spleen.[390] Splenic infarction in young children with SCA is an insidious process (usually with few symptoms) but is also progressive and culminates in splenic dysfunction. In older children and adults, especially those with HbSC and HbSβ^+-thalassemia, severe left upper quadrant pain often accompanies acute splenic infarction. Transfusion,[391] hydroxyurea,[392,393] and bone-marrow transplantation[394] can correct the splenic phagocytic defect, although these treatments are not indicated for splenic dysfunction per se.

Children with functional asplenia fail to respond to intravenously administered antigen vaccines,[395] even when the phagocytic function of the spleen has been restored by transfusion. As with other individuals with asplenia, however, these children do respond normally to intramuscularly/subcutanously administered polysaccharide and conjugated pneumococcal vaccine.[396-398]

Levels of serum immunoglobulins are normal or increased in children with SCA.[397,399,400] However the serum is deficient in heat-labile opsonizing activity[401] related to an abnormality of the properdin pathway,[402,403] which is specific for the phagocytosis of pneumococci. There is an increased activation of complement via the alternate pathway[404] but no intrinsic defect in the complement system.[405] Opsonic activity can be reconstituted in vitro by addition of only the $F(ab')_2$ fragments of capsular antibodies to *S. pneumoniae*.[406] This abnormal opsonic activity and associated functional asplenia may partially explain the propensity for infections with pneumococcus and other encapsulated organisms.

Recurrent pnuemoccocal infections have been described in patients with SCD.[407] In one series patients with serious invasive bacterial infections are significantly more likely to have recurrent infection.[408]

Treatment of Infection

Because of the increased incidence of serious bacterial infections in patients with SCD, the index of suspicion for infection should always be high. In general the higher the temperature[409] and leukocyte count,[410] the higher the probability of a serious bacterial infection. Unfortunately however, the wide variability in the temperature and laboratory values of children with bacteremia does not permit an accurate prediction of whether an individual febrile child is bacteremic. The following guidelines are adapted from the NHLBI guidelines for empiric evaluation and treatment of the febrile child with a temperature higher than 101.3° F (38.5° C)[411]:

- Perform complete blood cell count, reticulocyte count, blood culture. Consider urine and throat culture based on signs or symptoms. Perform chest radiography if pulmonary signs or symptoms are present.
- Prompt administration of broad-spectrum empiric parenteral antibiotics that provide coverage against *S. pneumoniae* and gram-negative enteric organisms before the results of laboratory tests are available or radiographs are taken. Empiric antibiotic selection should be based on the ability to kill both pneumococcus and *H. influenzae* and to penetrate the CNS. In areas where β-lactamase-producing *H. influenzae* or penicillin- and cephalosporin-resistant pneumococci are regularly encountered, these issues should be factored into the choice of antibiotic.
- Typically after antibiotic administration (e.g., ceftriaxone, 50 to 75 mg/kg, parenterally) the patient should be observed over 2 to 6 hours. Subsequent outpatient management is feasible in patients who do not appear to have toxic reactions or other features to consider for admission. Follow-up evaluation the next day and possibly repeat the empiric antibiotic dose.[412] If children do well and culture results remain negative after 24 to 48 hours, antibiotics can be discontinued.
- Admission to hospital and continuation of empiric parenteral antibiotic treatment should be considered for:
  - Appearance of toxicity
  - Temperature higher than 40° C
  - Infiltrate on chest radiograph
  - WBC count higher than $30{,}000/mm^3$ or below $500/mm^3$, platelet count less than $100{,}000/mm^3$, or Hb below 5 g/dL
  - History of prior bacterial sepsis should be treated parenterally and patient should be admitted to the hospital.
  - Previous surgical splenectomy
  - Incomplete vaccination to pneumococcus or *H. influenzae*
- Lumbar puncture should be performed on children having toxic reactions and those with any signs of meningitis. Bacterial meningitis should be treated for a minimum of 10 days parenterally or for at least 1 week after the cerebrospinal fluid has been sterilized.
- Documented sepsis should be treated parenterally for a minimum of 1 week.
- Patients with infiltrate on the chest radiograph should be treated as described for ACS. Because of the high incidence of atypical pathogens, patients should be treated with an appropriate antipneumococcal agent and macrolide antibiotic for at least a week.

Despite advance in laboratory and imaging techniques, the diagnosis of osteomyelitis in SCD is often difficult to distinguish from aseptic bone infarct and still relies heavily upon clinical assessment.[211] Patients with clinical findings that are highly suggestive of osteomyelitis should have needle aspiration and culture of the lesion. After cultures have been obtained, children who appear acutely ill should be started on antibiotics. Antibiotic choice should include agents effective against *Salmonella* species and *Staphylococcus aureus*. Antibiotics should be discontinued or modified when culture reports are available.

Prevention of Infection

Methods of preventing invasive bacterial infection in SCA patients have focused on prophylactic antibiotics and vaccines. Prophylactic penicillin was first shown to be effective in the prevention of pneumococcal disease by John and associates,[413] who used monthly intramuscular injections of long-acting penicillin. However if penicillin prophylaxis was discontinued after 3 years of age, an increase in pneumococcal infections was noted. Gaston and co-workers, in a blinded placebo-controlled clinical trial in the United States, showed that 84% of the pneumococcal infections in children younger than the age of 5 years could be prevented with oral penicillin.[414] As a result of this landmark study, universal newborn screening has emerged throughout the United States, so that all children with SCA can be identified and started on penicillin prophylaxis by 3 months of age. If penicillin is discontinued after 5 years there is no increased incidence in infections compared to those who remained on prophylaxis;[415] and there are conflicting data regarding the increased risks of penicillin-resistant pneumococcal colonization while on prophylaxis.[416,417] Our approach to prophylaxis is as follows:

- Give prophylaxis to all newborns with HbSS, HbS β-thalassemia, and HbSC disease. (Some practitioners prefer not to treat infants with HbSC disease because their splenic dysfunction typically appears later in life.)
- Start as early as possible, optimally by 8 weeks of age but certainly by 3 months.
- Prescribe penicillin, 125 mg orally, twice a day until age 3 years. Then increase the dose to 250 mg orally, twice a day. Penicillin can be stopped after 5 years of age without resulting in an increased incidence of infection. Consider continuation for history of invasive bacteremia or surgical splenectomy.
- For patients allergic to penicillin, prescribe erythromycin, 10 mg/kg orally, twice a day.
- Educate families as to the importance of compliance and the early recognition of signs of infection, particularly temperature of 101.3° F (38.5° C) or higher.
- For vaccination recommendations, consult the Advisory Committee on Immunization Practices (ACIP) statements for detailed up-to-date recommendations for SCD.[418] Complete routine vaccination schedule including complete conjugated vaccine series for *S. pneumoniae* (Prevnar-13; PCV13) and *H. influenzae*. Polyvalent pneumococcal vaccine has been shown to be effective in eliciting a normal antibody response, increases in pneumococcal opsonizing activity, and reducing the incidence of pneumococcal disease.[404,419] The 23-valent polysaccharide pneumococcal vaccine (Pneumovax; PPV23) represents 90% of the common serotypes of pathogenic pneumococci, however, because children younger than 2 years have a poor response to this vaccine[420] it should be given at age 2 years with a booster 3 to 5 years later. *H. influenzae* conjugated vaccine is immunogenic in children with SCD and should be given on the same schedule used for normal infants.[421,422] Seasonal influenza vaccine should be administered to all SCD patients annually. Conjugated meningococcal vaccine (Menactra; MCV4) should be administered to patients at age 2 years.

Despite established strategies of penicillin prophylaxis and conjugated vaccines, invasive bacterial infections continue to occur in patients with SCA, sometimes because of pneumococcal serotypes not included in the vaccines.[423-425] Although the incidence of penicillin-resistant pneumococcus has not been demonstrated in patients receiving prophylaxis, there appears to be an emergence of multidrug resistant pneumococcus in patients treated longer than 5 years.[416] Physicians must continue to emphasize the need for penicillin and vaccination compliance and continue to have a high index of suspicion of sepsis in the febrile child with SCD.

Chronic Organ Damage

Cardiovascular System

Abnormal cardiac findings are present in most patients with SCA[426-429] and are primarily the result of chronic anemia and the compensatory increased cardiac output.[430] On physical examination, the most common finding is systolic ejection murmur, although concomitant S_3, split S_1, suprasternal notch thrill, and diastolic murmur may also be present.[426] Echocardiography may be necessary to diagnose abnormal cardiac structure. Cardiomegaly is common, with electrocardiographic findings of left ventricular hypertrophy in about 50% of patients.[427]

In view of the fact that the hallmark of SCD is vaso-occlusion, it is remarkable that myocardial infarction is an extremely rare event.[427,431,432] In one review of the postmortem literature related to SCD including examination of 153 hearts, only four infarcts were reported.[431] Despite the high oxygen extraction in the coronary circulation, blood in the coronary sinus contains no more sickled forms than the general circulation,[433] presumably because of the short transit time through the coronary vessels.[430] Atherosclerosis is virtually absent in this population, and the SCD heart has normal patent coronary arteries, often of larger caliber than seen in normal hearts.[434]

The most comprehensive prospective examination of cardiac function in an unselected population of patients with SCA was done in the CSSCD.[435] One hundred and ninety one patients ages 13 and older in steady state underwent echocardiography, and all of the measurements were performed centrally by an investigator without access to other patient data. After appropriately adjusting for body surface area, the left and right ventricles, aortic root, and left atrium were found to be larger than normal. Significant wall thickening was found only in the septum. The left ventricular dilation correlated with Hb and age, suggesting that the major cardiac findings are indeed related to the years of increased stroke volume in compensation for anemia and abnormal rheology.

PHT can occur in adult patients with SCD, both as a result of cardiac dysfunction and also from intrinsic pulmonary vasculopathy, with a reported prevalence as high as 20% to 40% based on tricuspid regurgitant jet velocity (TRJV) measurements.[436-439] Multiple retrospective studies report a significantly increased mortality in patients with SCD and elevated TRJV compared with those patients without this finding.[437,440,441] Castro et al. demonstrated that patients with SCD and PHT confirmed by right heart catheterization had median survival of 25.6 months, whereas patients without PHT had greater than 70% survival at the end of a 10-year observation period.[441] A more recent study of 195 patients with SCD reported a significantly higher mortality rate for adult patients with TRJV (>2.5 m/s on echocardiography after a median follow-up length of 18 months).[439] Increased lactate dehydroenase (LDH), bilirubin, and reticulocyte count have been associated with the elevated TRJV findings, which

Data from Pegelow CH, Colangelo L, Stunberg M et al. Natural history of blood pressure in sickle cell disease. Am J Med *102:171–177, 1997.*

has led to a hypothesis that increased hemolysis is responsible for the vasculopathy.[439,442] Because intravascular hemolysis leads to increased plasma Hb and arginase, which are associated reduced NO bioavailability (see Hemolysis and Nitric Oxide Depletion), subsequent endothelial dysfunction and PHT could result from this pathophysiology.[443] The prevalence of elevated TRJV in children appears similar to that in adults[444-446]; however, a recent French adult study revealed a prevalence of 27%, but confirmation by catheterization revealed that PHT prevalence was only 6%. Therefore the positive predictive value of TRJV greater than 2.5 m/s appears low.[447] Further concerns about the reproducibility of TRJV measurements in children,[448] as well as the prognostic implications that differ from adults, have prevented the development of screening recommendations among children with SCA.[448,449]

The steady-state blood pressure in patients with SCA (and to a lesser extent all forms of SCD) is lower than in a race-, gender-, and age-matched normal population (Table 20-3).[321] This observation may reflect differences in peripheral vascular resistance or be related to the tendency to lose sodium and water in the urine. Higher blood pressure is a risk factor for stroke, early mortality, and nephropathy,[450] but the diagnosis of elevated blood pressure depends on knowing the normal values for this population (see Table 20-3). The clinician should note that blood pressures that appear to be normal based on race, gender, and age could be significantly elevated and clinically ominous in the sickle population. Such patients should be considered candidates for antihypertensive therapy.

Renal System

Hyposthenuria, hematuria, nephrotic syndrome, and uremia are the major renal complications of SCD.[451,452] In addition the production of erythropoietin in response to anemia may be lower in older patients with SCA, possibly because of primary renal disease.[453]

Hyposthenuria develops early in childhood, and as is the case with functional asplenia, may be temporarily reversed with transfusion.[454-457] The hypertonic environment of the renal medulla promotes intraparenchymal sickling even at normal pO_2,[458] which leads to decreased medullary blood flow and derangement of the countercurrent multiplier. Abnormality of the countercurrent multiplier may be the mechanism for hyposthenuria, or as suggested by Buckalew and Someren,[451] it may be the result of decreased flow to nephrons with long loops of Henle and preservation of flow to nephrons with short loops. The obligatory water loss in SCA results in a tendency toward dehydration and invalidates the use of urine volume or specific gravity as an indicator of the patient's state of hydration. Nocturia and enuresis are common complaints of these patients, who excrete large volumes of dilute urine.[459] Urinary sodium losses may be high and result in significant hyponatremia.[460] A renal tubular acidification defect[461,462] as well as hyporeninemic hypoaldosteronism[463] and impaired potassium excretion[464] have been identified. In one review deJong and Van Eps emphasized that renal vasodilating prostaglandins are increased in patients with SCD, leading to a compensatory increase in renal blood flow, glomerular filtration rate (GFR), and proximal tubular activity.[465]

Although hematuria is usually mild, overt bleeding is occasionally severe enough to cause significant blood loss.[466] Papillary necrosis is usually the underlying anatomic defect.[467] Maintenance of high urinary flow with increased fluid intake will eliminate clots from the bladder and decrease medullary osmolality. Urinary alkalinization and diuretics may be beneficial until the bleeding stops. ε-Aminocaproic acid has been suggested to treat severe hematuria that is refractory to supportive care and transfusion,[468] but it must be used cautiously because of the risk of ureteral or pelvic clotting and obstruction. In patients with long-standing hematuria, supplemental iron may be necessary to prevent iron deficiency. Hematuria may also be the presenting symptom of a renal tumor. A surprisingly high incidence of renal medulary carcinoma has been reported in patients with SCD and even persons with sickle trait.[469,470]

Uremia is a rare complication in children with SCD that may follow a symptom complex of nephrotic syndrome[471] with glomerulonephritis. The nature of the glomerular lesion is unknown and may represent response to iron deposition,[472] antigen-antibody complex,[473] or mesangial phagocytosis of fragmented sickled cells.[474,475] Recently an association between parvovirus infection with or without an antecedent aplastic crises has been associated with acute glomerulonephritis.[377,378]

Proteinuria in SCD begins in childhood and teenage years and can progress to nephrotic syndrome[476] and ultimately to renal failure,[475,477] which is a common cause of mortality among adults with SCA.[131,478] Microalbuminuria manifested by a ratio of albumin to creatinine (>20 mg/g Cr) is common; a study of 442 children with SCD studied for 10 years reported proteinuria in 6.2% of children and 12% of teenagers.[479] Proteinuria was associated with lower Hb levels, higher MCV, higher white cell counts, and more clinically severe disease. A study of 381 adults with SCD demonstrated that 7% had elevated serum creatinine levels and 26% had proteinuria.[480] Ten patients with proteinuria underwent renal biopsy, and the glomerular lesions showed perihilar focal segmental sclerosis and glomerular enlargement, similar to findings in an animal model with glomerular hypertension and efferent arteriolar vasoconstriction. To test the animal analogy, these patients were treated with enalapril, an angiotensin-converting enzyme (ACE) inhibitor that has been shown to decrease efferent arteriolar constriction. In all treated patients the level of proteinuria fell during treatment and returned toward abnormal after discontinuation.

The predictive value of microalbuminria screening has not been fully elucidated in children but has been suggested by some.[481,482] Serum cystatin C may be a better screen for GFR than creatinine in SCA, because it appears to rise according to the degree of albuminuria and before significant elevation in serum creatinine is detected.[483]

Treatment of microalbuminuria[484] or proteinuria[480] with ACE inhibitors can be effective, but long-term therapeutic benefits for the prevention of progressive glomerular disease have not yet been demonstrated.[485] Addition of hydroxyurea to ACE inhibitors may further improve renal function.[486]

Bakir and associates estimate that 4% of adult patients with SCA develop nephrosis and that two thirds of these patients go on to develop renal failure.[475] Renal failure can be managed with peritoneal dialysis, hemodialysis, and transplantation. Renal transplantation can be successful in patients with end-stage sickle nephropathy, but three-year allograft and patient survival are significantly decreased compared with other patient populations.[487]

Hepatobiliary System

Liver and biliary tract abnormalities are common in SCD[488,489] and are the result of cholelithiasis, hepatic infarction, and transfusion-related hepatitis and hemosiderosis.

Bilirubin gallstones are common,[490,491] and two large series have studied the incidence of gallstones as detected by ultrasound in children with SCA.[492,493] The percentage of gallstones in 226 patients aged 5 to 13 years selected randomly from a group of children with HbSS disease identified at birth was 13%,[488] a value lower than that found in a survey of clinic patients studied by Sarnaik and associates.[492] In this report, the incidence of gallstones was 12% by 2 to 4 years of age.[492] With advancing age, the incidence increased gradually, reaching 42% in the 15- to 18-year-old age group. Fourteen of the 226 patients were noted to have “sludge” in the gallbladder, and on repeated ultrasonograms up to 2 years later, four had developed stones, 4 had no further evidence of sludge, and 6 remained unchanged. Comorbid Gilbert syndrome (uridine diphosphate [UDP]–glucuronosyltransferase 1A1 [UGT1A1] promoter polymorphism) significantly increases the serum bilirubin levels in children with SCD and the likelihood of requiring early cholecystectomy.[168] Evidence is good that children tolerate elective cholecystectomy with little morbidity if they are prepared properly for surgery.[263,494,495] Laparoscopic cholecystectomy has been particularly effective in reducing the postoperative hospital stay in children with SCD.[496] In contrast operating during the acute phase carries a significant risk of complication. [263,497]

Intrahepatic sickling can result in massive hyperbilirubinemia,[261] elevated liver enzyme values, and a painful syndrome mimicking acute cholecystitis[262] or viral hepatitis.[490] (See “Acute Abdominal Pain”). Fulminant hepatic failure with massive cholestasis and rapidly progressing hepatic encephalopathy and shock has been described as a rare but often fatal complication of SCD that may be amenable to exchange transfusion.[264,498,499]

Eyes

SCD can affect virtually every vascular bed in the eye.[500] Tortuosity and sacculation of conjunctival vessels are seen in more than 90% of patients with SCD. These lesions are best seen in the lower temporal area, disappear after exchange transfusion, and are curiously related to the ISC count in the peripheral blood.[501] They are purely cosmetic, however, and have no deleterious effect on the eye.

Sickle retinopathy is classified as either proliferative or nonproliferative. Nonproliferative retinopathy probably results from retinal arteriolar infarction with adjacent hemorrhage and requires no therapy. Depending on the age, layer, and extension of the hemorrhage, the result can be a salmon patch, schisis cavity, vitreous hemorrhage, or black sunburst.[502] In two patients with documented acute arteriolar occlusion, salmon patches developed in a matter of hours to days, with atrophic schisms cavities evolving in 3 to 4 months.[367] In older patients angioid streaks are common, but the cause is unknown.[503,504]

The more serious complication is proliferative retinopathy, which has been classified by Goldberg[505] as stage 1, peripheral arteriolar occlusions; stage 2, arteriolar-venular anastomoses; stage 3, neovascularization; stage 4, vitreous hemorrhages; and stage 5, retinal detachment. Because these lesions may progress to blindness, laser therapy to occlude feeding vessels of advanced proliferative lesions has been advocated. Unfortunately photocoagulation carries the risks of neovascularization of the choroid[506] and retinal breaks,[507] and complications that can result in blindness. The dilemma of choosing potentially blinding therapy for a potentially blinding lesion is complicated by the observation that some proliferative lesions heal spontaneously by autoinfarction. In one study of untreated sickle retinopathy in Jamaica, 567 eyes were observed for 8 years.[508] Proliferative retinopathy was initially present in 12% of the eyes: another 8% developed retinopathy during the follow-up study, and patients with HbSC were more commonly affected than those with SCA. Blindness resulted in 12% of the eyes with retinopathy. In the original group of eyes with retinopathy, 30% developed progressive retinopathy, 10% showed spontaneous regression, and the remaining 30% showed a mix of regression and progression. In another prospective Jamaican study, treatment of retinopathy was compared with no treatment.[509] No statistical difference in visual acuity between the two groups was reported. Macular ischemia and color blindness have been reported to be prevalent in patients with SCD without evidence on ophthalmologic examination of retinal lesions.[510,511]

Rarely acute painless loss of vision is the result of central retinal artery occlusion. Although such lesions may resolve spontaneously, exchange transfusion has been recommended for bilateral disease.[512]

Blunt trauma to the eye may result in hyphema (bleeding into the anterior chamber). Because the conditions in this chamber overwhelmingly favor sickling, any HbS-containing red cell will sickle (even sickle trait) and may cause obstructive glaucoma and blindness. Common medical treatments that might be considered in patients without SCD may promote sickling and should be avoided (e.g., hyperosmotic/diuretic agents/carbonic anhydrase inhibitors). Initial topical β-adrenergic antagonists (e.g., timolol) or α_2-adrenergic agonists (e.g., brimonidine) may be effective,[513] but a low threshold for surgical evacuation of anterior chamber blood should be observed so that vision is preserved.[514] This condition is one of the true ocular emergencies that occurs in patients with SCD as well as sickle trait.

Skin

Leg ulcers usually do not occur in childhood, but in adolescence and adulthood ulcers may constitute a crippling symptom. This skin lesion is also very rarely seen in other chronic hemolytic anemias such as hereditary spherocytosis, thalassemia, elliptocytosis, and pyruvate kinase deficiency[515] and therefore may not represent a vaso-occlusive phenomenon. Ulceration may result from increased venous pressure in the legs caused by the expanded blood volume in the hypertrophied bone marrow.[516] In tropical areas in which shoes are not usually worn and insect bites are common, leg ulcers are also common.[517] In Jamaica, leg ulcers typically start in the 10- to 20-year-old group and eventually appear in 75% of adults. Koshy and colleagues[518] have reported data from the CSSCD regarding leg ulcers in patients with SCD. Leg ulcers appear to be less common in individuals with two α-globin genes than with those with three or four genes. The incidence of leg ulcers appears to decrease consistently with increases in HbF production.[518] There is decreased venous outflow in in the lower extremities of patients with leg ulcers compared with patients without ulcers, suggesting that venous incompetence may contribute to the development or failure to heal of these lesions.[519] In addition, low steady-state Hb values and markers of high hemolytic rate are associated with increased incidence of leg ulcers and may be associated with decreased NO bioavailability and endothelial dysfunction.[520,521]

Chronic leg ulcers become a major source of morbidity and have a profound negative impact on educational achievement and employment.[522] Usually present over the medial surface of the lower tibia or just posterior to the medial malleolus, they begin as a small depression with central necrosis and, if unattended, widen to encircle the entire lower leg. Debridement, scrupulous hygiene, topical antibiotics, bed rest, and elevation of the leg are the mainstays of therapy. In some patients, protection of the ulcer by the application of a soft sponge-rubber doughnut and a low-pressure elastic bandage seems to be beneficial. One report suggested that an arginine-glycine-aspartic acid (RGD) peptide matrix designed to mimic the normal matrix was beneficial.[523] Close attention to improved venous circulation by the use of above-the-knee elastic stockings may prevent ulceration. If ulcers persist despite optimal care, transfusion therapy may be used and consideration given to split-thickness skin grafts. Transfusion therapy is sometimes effective, but in many patients the ulcers either do not heal or recur after discontinuation of this therapy. Oral zinc sulfate may promote healing of leg ulcers,[524] and peripheral vasodilator therapy appears ineffective.[525]

Skeleton

Skeletal changes in SCD are common[201,211,526,527] and are the result of expansion of the marrow cavity and repeated bone infarction. The expanded marrow is best seen in radiographs of the thickened calvarium with a wide diploic space. Overgrowth of the anterior maxilla may lead to severe orthodontic and cosmetic problems. Vertebrae are generally flattened, with a characteristic biconcave deformity called *codfish vertebrae*. In older patients, vertebral disease may cause chronic back pain. These individuals need to be treated as other patients who have chronic back disease with appropriate exercises, braces, bed rest, muscle relaxants, and moral support.

The major chronic bone complication of SCD is AVN. Indeed, the most common etiology of AVN of the femoral head in children is SCD. As shown (Fig. 20-8), the incidence is relatively low in children, with a prevalence estimated at 3% in children under 15 years, but increases with age and occurs in both patients with SCA and HbSC disease.[528] The incidence is remarkably increased in patients with SCA and α-thalassemia, who also have higher hematocrit levels and rates of pain.[151] Athophysiology of AVN is unknown but hypothesized to result from limited blood supply in the femoral (and humeral) heads that promotes sludging in marrow sinusoids, marrow necrosis, healing with increased intramedullary pressure, articular surface necrosis, bone resorption, and eventually epiphyseal collapse.[151,529] The diagnosis is often made clinically with pain and limited range of motion or radiographically, classically with a spectrum of findings from subepiphyseal lucency and widened joint

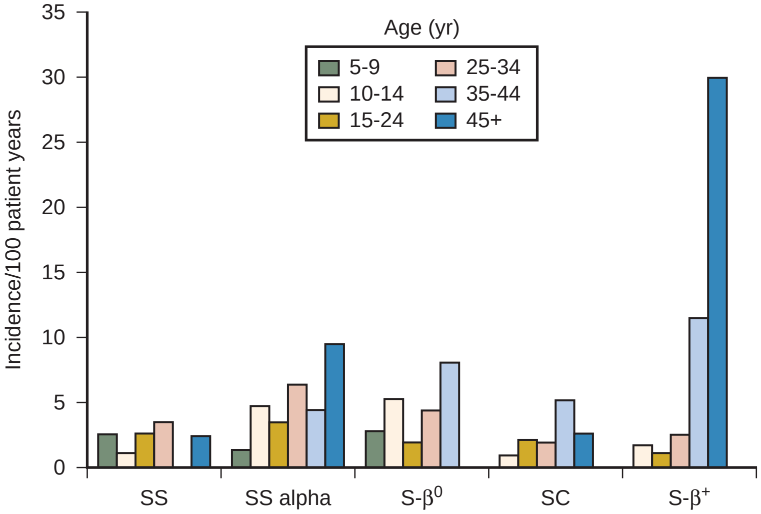

Figure 20-8 Incidence of osteonecrosis of the femoral head per 100 patient years by genotype. *(Data from Milner PF, Kraus AP, Sebes JI et al: Sickle cell disease as a cause of osteonecrosis of the femoral head.* N Engl J Med *325:1476–1481, 1991.)*

space to flattening or fragmentation and scarring of the epiphysis. Although roughly half of the patients diagnosed on the basis of screening radiographs were clinically asymptomatic, significant chronic pain and limited joint mobility plagued the others. MRI can identify AVN changes earlier than conventional films.[528,530]

Managing osteonecrosis of the femoral head in young adults is a challenging problem with limited treatment options and often disappointing outcomes. Strict bed rest and limited weight bearing are helpful to some patients,[531] with little or no evidence to support the use of chronic transfusion therapy, core decompression,[532] bone grafting,[533] or injection of autologous bone marrow[534] or cement.[535] A randomized prospective study of hip core decompression versus physical therapy for the treatment of early femoral head osteonecrosis revealed clinical improvement in both groups, but one was no more effective than the other.[536] Despite interventions to preserve the femoral head, progression is common and may result in the need for total hip replacement arthroplasty for severely compromised patients. In the study of Milner and colleagues, 17% of patients underwent hip replacement, 30% of replaced hips required surgical revision within 4.5 years, and more than 60% of patients continued to have pain and limited mobility postoperatively.[151] The epidemiology of AVN of the humeral head is virtually identical to that of the femur.[537] In general, however, the patients are less symptomatic because of reduced weight bearing, and shoulder arthroplasty is not required.

Lungs

In contrast to ACS, chronic sickle lung disease has been more difficult to define and quantitate, with many conflicting studies showing restrictive or obstructive defects or both. Furthermore the relationship between ACS and chronic lung disease has been difficult to establish reproducibly. In older children, lung volumes are reduced[538,539] when compared with those of a normal white population but are appropriate when compared with those of a black control population.[540] An early restrictive and obstructive pulmonary function pattern has been reported in children with SCD,[541,542] and there appears to be an emerging link between obstructive lung disease and ACS pathogenesis, particularly in children.[247,256,543,544] In a study of infants 3 to 30 months of age restrictive lung disease was present in 3 out of 12 infants and was not related to a history of ACS.[545] These studies suggest that subtle subacute damage to the lungs proceeds even in the absence of acute disease. Hydroxyurea therapy[243] reduces the incidence of recurrent ACS and can improve chronic hypoxemia.[546] In 24 patients with a history of chest syndromes studied after bone marrow transplant, 22 showed no improvement and 2 patients showed worse pulmonary function posttransplant.[547]

Central Nervous System

Acute neurologic abnormalities in SCA were discussed earlier. Kral et al found that children with SCD perform more poorly on measures of neurocognitive functioning with increasing age or lower hematocrit levels[548] and that transcranial Doppler ultrasonography was the only radiologic measure that could predict neurocognitive outcome after controlling for age and hematocrit. It is now clear that cognitive functioning and fine motor skills are also impaired in patients with silent cerebral infarcts as diagnosed by MRI[316,549]; however, no established relationship exists between SCI and abnormal TCD or MRA imaging.[318] Cognitive deficits remain even in the absence of cerebral infarction.[550] Because abnormal TCD and/or MRI studies can be seen in children with decreased neurological and/or cognitive performance, these radiologic studies are being considerd as screening tools to select very young patients for experimental therapies that may prevent further CNS damage.[322-324]

Growth and Development

The birth weight of infants with SCA is normal.[551] Subsequently a pattern of delayed growth emerges. Detailed

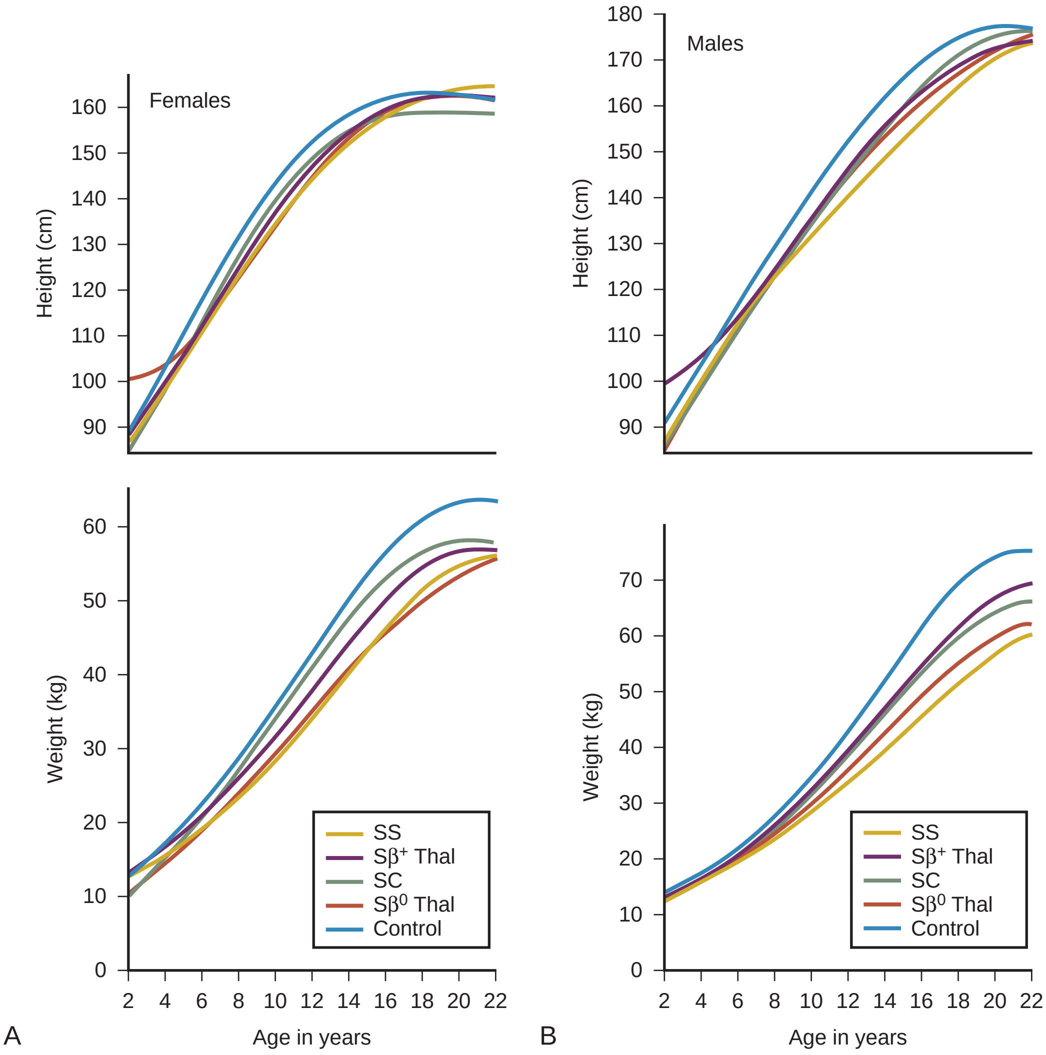

Figure 20-9 Height and weight growth curves for females (**A**) and males (**B**) 2 to 22 years of age, according to type of hemoglobinopathy. Shown are the 50% curves. *(From Platt OS, Rosenstock W, Espeland MA: Influence of sickle hemoglobinopathies on growth and development.* N Eng J Med *311:7–12, 1984.)*

anthropomorphic measurements of Jamaican children reveal decreased limb length, sitting height, and skinfold thickness, with increased chest anteroposterior diameter[552] that is possibly related to cardiomegaly.[553] Height and weight growth curves for individuals with SCD in the United States were generated as part of the CSSCD sponsored by the NHLBI (Fig. 20-9).[554] The important features of these curves are that they are different from those for normal black controls in that weight is more affected than height and that patients with SCA experience more delay in growth than patients with other forms of SCD. In general by the end of adolescence, the patients with SCD have caught up with controls in height but not weight. The reason for this poor weight gain is not understood but is likely to represent increased caloric requirements of elevated resting energy expenditure related to anemia, increased bone marrow activity, and cardiovascular compensation.[555] In a second large prospective study in Jamaica, both height and weight were significantly lower than that of age- and sex-matched controls as early as 2 years of age.[556] A more recent study reveals that body mass index (BMI) percentiles for children with SCA in New England are higher than historically reported, mimicking the rise in BMI in the general pediatric population. The odds of being overweight or obese were increased in the children with higher baseline Hb levels.[557]

Zinc deficiency has been suggested as a cause of poor growth in children with HbSS disease[558,559] but has not been confirmed.[560] Levels of vitamins A, B6, and D have been discovered to be lower than in ethnically matched children and may relate to morbidity.[561,562] Growth hormone deficiency is a rare and reversible cause of growth delay.[563] In general growth hormone levels and growth hormone stimulation studies appear to be normal in children with HbSS disease who have impaired growth.[564] A review of nutritional studies in patients with SCA is available,[565] and one study has suggested that hyperalimentation may be useful in some patients.[566]

Sexual development is also delayed in patients with SCD.[554] This delay is found in both males and females

TABLE 20-4 Estimated Median Age at Attainment of Tanner Stages According to Hemoglobinopathy

	Tanner Stage	Median Age			
		SS	SC	S-β$^+$	S-β^0
Females					
Breasts	2	11.8	9.8	10.6	11.8
	3	13.5	11.9	12.6	12.8

S-β$^+$, S β$^+$-thalassemia; *S-β^0*, S β^0-thalassemia; *SC*, sickle cell disease; *SS*, sickle cell anemia.

and follows the same pattern as height and weight in other hemoglobinopathies. The estimated median age of attainment of Tanner stage for each hemoglobinopathy is listed in Table 20-4. For females (regardless of hemoglobinopathy), menarche status is a function of age and weight. This normal relationship between menarche and weight suggests that in females, delayed sexual maturity is constitutional. Most males have delayed sexual maturation, also suggesting constitutional delay.

Psychological Aspects

Although most patients with SCD handle their illness very well, patients and families require strong, empathetic support and screening for psychological stressors. As with any chronic disease, given the physical and psychosocial burdens that children with SCD and their families experience, it should not be surprising that they may exhibit psychological dysfunction[567-569] and impaired family functioning.[570,571] It is estimated that between one third to two thirds of children with SCD experience significant psychological symptoms and impaired health-related quality of life (HRQoL).[567,572-575] Dampier and associates[576] found that children and their parents scored significantly lower on several HRQoL domains, including general physical, motor, and independent daily functioning. Children with SCD tend to have deteriorations in social and school competence compared with healthy peers, but this is not associated with disease severity or genotype.[573]

Medical stressors in SCD not limited to pain (e.g., inability to keep up with peers, delayed growth/puberty, and fears of premature death) and psychosocial factors (e.g., low socioeconomic status, poor family functioning) will challenge a child's ability to adapt.[575] To manage these stressors, patients and families use a range of approaches and avoidance-oriented coping strategies.[577]

MORTALITY

Although much is known about the risk factors for early mortality in SCA the disease severity remains higly heterogeneous, and risk stratification of individual patients is challenging. Patients with a higher level of HbF have a longer life expectancy,[131] as do those with a low rate of pain crisis,[131] a low rate of ACS,[132] no hand-foot crisis before age 1 year,[133] no severe anemia before age 2 years,[131,133] a low baseline WBC count,[133] and low blood pressure.[321]

Leikin and colleagues examined mortality in a cohort of children in CSSCD.[578] They found that the peak incidence of death was between 1 and 3 years of age and was generally caused by infection. The overall mortality rate was 0.5 deaths per 100 patient years, and for patients with SCA, the probability of surviving to age 29 years was about 85%. For those with HbSC, the probability of surviving to age 20 years was about 95%.

As shown in Figure 20-10, when data on deaths of children from CSSCD are combined with data from adults, the median age at death was 42 years for males and 48 years for females with HbSS but 60 years for males and 68 years for females with HbSC.[131] Among adults, those with the lowest HbF levels, highest steady-state WBC counts, and highest rates of pain and chest syndrome had the highest risk of dying at an early age. There was an age-related pattern in mortality rates with a peak in the patients younger than 5 years of age and a gradual increase starting in late adolescence. Younger patients died primarily of pneumococcal disease and less often of acute splenic sequestration, ACS, or stroke.[382,579] Older patients die of ACS, during pain crises, chronic organ system failure from cancer and other specific diseases of adults, and suddenly without obvious cause.[131]

Quinn and colleagues reported a more recent experience from the Dallas Newborn Cohort[580] with an overall survival of 93.9% and an all-cause mortality rate of 0.52 per 100 patient years for children with SCA who were observed from birth through 18 years of age. In HbSC and S β$^+$-thalassemia their respective figures were 98.4% and 0.10 per 100 patient years. The Dallas cohort also showed trends of decreasing sickle-related mortality, increasing mean age at death, and a smaller proportion of deaths related to infection compared with the earlier CSSCD[192] and Jamaican[581] cohorts.

It is encouraging that coincident with the widespread use of prophylactic penicillin and conjugated vaccines in young children, early education and screening, aggressive treatment of pulmonary disease and infection, careful selection of patients for transfusion therapy, and thoughtful comprehensive care has coincided with

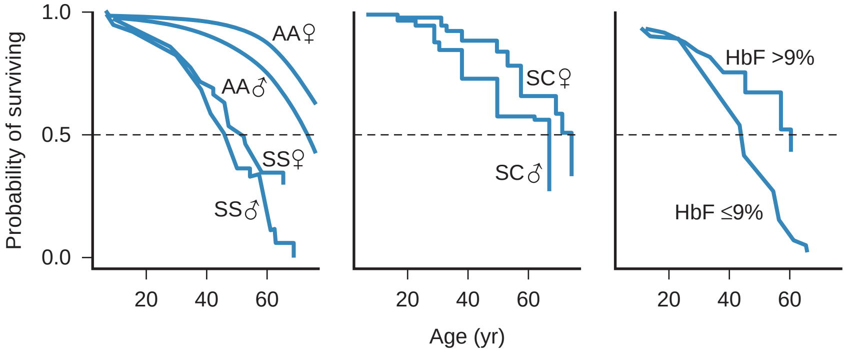

Figure 20-10 Survival of male and female patients with SS disease and SC disease, comparing those in the highest quartiles (>9%) of HbF level with the others. African-American (AA) controls are shown for comparison. *(Modified from Platt OS, Brambilla DJ, Rosse WF et al: Mortality in sickle cell disease: life expectancy and risk factors for early death.* N Eng J Med *330:1639–1644, 1994.)*

an improvement in survival among children,[582] though the long-term mortality of adults with SCD remains foreshortened.

APPROACHES TO THERAPY

The NHLBI published its fourth edition of *The Management of Sickle Cell Disease* in 2002,[411] and an update is expected.[583] The following descriptions are based on these evidence-based guidelines that reflect prospective research findings as well as expert opinion and consensus.

Routine Health Maintenance

Infants diagnosed by newborn screening should be referred to pediatric hematologists for confirmation of the diagnosis and genetic counseling. Health maintenance visits to a pediatric hematologist should occur on a routine basis (Table 20-5). In the first year after diagnosis they should be scheduled for every 3 months with a focus on intensive parental education and provision of written materials. Subsequent routine visits should occur every 6 months, although higher frequency visits may be required for patients with increased educational needs, accumulated complications, and therapeutic monitoring (e.g., hydroxyurea and/or chronic transfusion therapy). Regular visits allow the practitioner to record baseline physical findings (e.g., vital signs, SpO_2, icterus, murmurs, organomegaly) and baseline laboratory studies (e.g., complete blood count, reticulocytes, chemistry). These baseline data are extremely important in the recognition of an acute complications, and routine visits afford the opportunity for education and anticipatory guidance.

Careful evaluation of the interval history may provide insight into factors that provoke painful crises. Continuing disease counselling of patients and families regarding basic pathophysiology, avoidance of triggers, and early recognition/home treatment of the wide variety of complications of SCD will reduce the morbidity and hospitalization rate and will promote the patient's and family's sense of independence. Disease education should also include genetic counseling of the parents with the goal that they understand the risks of SCD in future pregnancies.

Careful attention is paid to prevention of bacterial infections including vaccinations and prophylactic penicillin (see Prevention of Infection). All children with SCD should receive the complete routine immunization schedule according to the Advisory Committee on Immunization Practices (ACIP)[418] that includes conjugated pneumococcal, conjugated *H. influenzae,* and hepatitis B vaccines. Additional vaccines including the 23-valent pneumococcal polysaccharide vaccine (Pneumovax; PPV23), seasonal influenza vaccine, and conjugated meningococcal vaccine (Menactra; MCV4) should be administered. Prophylactic penicillin should be given to all children younger than 5 years of age.[414] Most importantly the patient and family should be educated about the importance of early detection, medical evaluation, and empirical treatment of a possible bacterial infection triggered by a temperature of 101.3°F (38.5°C) or higher.[411]

Although supplemental folic acid (1 mg/day) is recommended in chronic hemolytic anemias to prevent folate deficiency and maintain effective erythropoiesis, no definite advantage has been seen in children with SCA.[584] Given that the United States has been fortifying foods with folic acid for more than 20 years as part of a public health effort to prevent neural tube defects, the need for additional supplementation is less compelling. Iron supplements are used only when iron deficiency is documented or when blood loss is chronic (e.g., hematuria).

Screening for renal disease should begin by age 10 years with assessment for microalbuminuria and proteinuria. If the result is negative, it should be repeated annually thereafter. If the result is abnormal, confirmation testing on first morning void within 1–2 weeks is suggested. If the repeat is abnormal, referral to a pediatric nephrologist should be made for consideration of ACE inhibitor therapy.

Screening for cardiovascular disease is limited to measurement of blood pressure with standard treatment for hypertension based on appropriate normal ranges for children. Routine screening electrocardiogram is not recommended for children. Screening aymptomatic children for elevated TRJV by echocardiography is controversial, and prognostic implications differ from adults; therefore screening recommendations in the pediatric age group have not been established.[448,449]

TABLE 20-5 Routine Health Maintenance for Patients with Sickle Cell Anemia*

*Shading indicates the time when the specified health maintenance should be performed.

Screening for primary stroke risk in SCA performed by specially trained ultrasonographers using TCD ultrasonography according to the STOP criteria is recommended annually. In children with conditional TCD values (170 to 199 cm/s) the frequency of screening should be increased. If TCD values are abnormal (>200 cm/s), referral to a specialist with expertise in chronic transfusion therapy aimed at preventing stroke is strongly recommended. Routine neurologic screening of asymptomatic children with SCA by brain MRI or CT is not recommended.

Screening for ophthalmologic complications with dilated eye examinations to evaluate for retinopathy should begin at age 10 years. A normal dilated retinal examination should be repeated at 1 to 2 year intervals; however, those with suspected retinopathy should be referred to a retinal specialist to establish the tempo of the lesion and to determine appropriate therapy.

Birth control options should be discussed as with any adolescent patient. Progestin-only contraceptives (pills, injections, and implants), levonorgestrel intrauterine devices (IUDs), and barrier methods have no restrictions or concerns for use in women with SCD.[585,586] If the benefits are considered to outweigh the risks, combined hormonal contraceptives (pills, patches, and rings) may be used in women of childbearing age.

Painful Crisis Management

Most painful crises can be successfully treated at home with increased oral fluid intake, heat to the affected area, and oral analgesics. If the pain is too severe for oral analgesics or if the patient cannot maintain adequate fluid intake, the episode must be treated in the hospital setting (day hospital, emergency room, or inpatient). Hospital management of painful crises must begin with a careful pain history, including recent analgesic use and consideration of nonsickle causes of pain, particularly if the pain is atypical by report of the patient. The mainstays of therapy are local strategies (e.g., heat, massage), IV hydration, and parenteral analgesia. In dehydrated patients, the fluid deficit should be corrected and then the IV fluid rate be set at 100% to 125% maintenance using a relatively hypotonic maintenance solution for age (e.g., D5 1/2 NS or D5 1/4 NS). However some patients cannot tolerate this expansion of intravascular volume, and the hydration rate may need to be tempered, particularly if oral fluid intake is adequate. Frequent monitoring of vital signs during fluid administration is essential to prevent pulmonary complications or cardiac compromise. If the patient is receiving primarily IV fluids, serum electrolyte levels should be checked early and fluid solutions adjusted appropriately. Although theoretically sound based on pathophysiology, the use of alkaline IV fluids has not been shown to be effective in uncomplicated painful crisis.[587]

Face-mask oxygen is of little therapeutic value unless the patient is hypoxic. Furthermore Embury and colleagues have shown that continuous supplemental oxygen can suppress erythropoiesis, with reticulocyte counts falling within days.[588] In addition painful crisis may result from the rebound marrow activity after the abrupt discontinuation of oxygen therapy.[589]

Analgesic selection should be based on pain assessment, associated symptoms, recent outpatient analgesic use, patient knowledge of effective agents and doses, and past experience with side effects. Analgesia must be sufficient to control the pain. Ideally an individualized prescribing and monitoring protocol provided by the patient's sickle cell provider or an SCD-specific practice guideline is available to promote rapid, effective, and safe analgesic management.[590] A general approach to analgesic choice should follow the World Health Organization (WHO) Pain Relief Ladder.[591] An initial trial of oral analgesics is reasonable if none was taken before presentation, with parenteral nonopioids (e.g., the nonsteroidal antiinflammatory drug [NSAID] ketorolac) as a common second tier. For patients in severe pain, rapid initiation of parenteral opioids is indicated, although standard doses may not be adequate to relieve an individual patient's pain, especially if the patient is not opioid naïve on presentation; therefore dosing should be titrated to relief. Analgesics and other adjuvants may be combined to optimize efficacy/safety.

One should choose opioids with knowledge of their side effects, drug interactions, serum half-lives, and previous efficacy. Difficult IV access may necessitate alternate routes of administration (e.g., intranasal, subcutaneous, transdermal) and may require adjustments for equianalgesic dosages. Serial intramuscular injections should be avoided and can lead to the formation of sterile abscesses. Meperidine is contraindicated, because accumulation of the toxic metabolite normeperidine may cause seizures, particularly in the setting of established cerebrovascular disease or compromised renal function.[592]

At the onset of inpatient therapy for severe pain, regular dosage intervals based on half-life should be used instead of an "as-needed" dosage strategy. This approach may avoid the recurrence of pain and anxiety as a result of delays in obtaining the next dose of medicine after being requested. Continuous IV opioid therapy in children has been successfully used,[593] but ACS may be precipitated by respiratory depression.[594] Perhaps an optimal approach is the use of patient-controlled analgesia[595,596] initiated in the emergency department[597] to provide adequate pain relief at a lower total opioid dose.[598] Continuation of NSAID therapy is helpful to most patients. Some have benefitted from nonpharmacologic adjuncts[599] such as acupuncture,[600] biofeedback,[601] cognitive therapy,[602] and hypnosis.[603]

Adverse effects of opioid analgesics include histaminergic (pruritus, hives), nausea, vomiting, constipation, and respiratory depression. Hypoventilation with progression to ACS is the most serious side effect of opioid therapy and must be fastidiously avoided by aggressive use of incentive spirometry,[604] encouragement of early ambulation, careful monitoring of SpO_2, and use of oxygen if the patient becomes hypoxic. In one study, epidural anesthesia was successfully used to alleviate pain and maintain or improve oxygenation.[605] Constipation is a common problem that should be anticipated, and stool softeners/cathartics should be started concommittently with opioids. Oral antihistamines are useful for the treatment of opioid-induced pruritus. Antinauseants and antiemetics may provide some relief if these side-effects are experienced. Urinary retention is not uncommon and may require bladder catheterization.

Sometimes it is virtually impossible to make a patient entirely comfortable with safe doses of opioids. This frustrating situation needs to be approached with care and sensitivity and with involvement of every member of the patient-care team.[606,607] For the rare patient who is incapacitated by recurrent episodes of pain and who spends more time in the hospital than out, chronic outpatient opioid therapy may be useful.[608] Although transfusion (even exchange transfusion) is rarely effective for acute pain, a brief maintenance program may facilitate completion of a school year or an important project at work; however, this must be tempered by risks of allosensitization, iron overload and bloodborne infection. Hydroxyurea is effective at decreasing the frequency of recurrent painful crises, but its favorable effect may be delayed by months or until the maxium tolerated dose (MTD) is reached.[243]

Although opioid dependence or opioid-seeking behavior may be a rare problem for pediatric patients, overestimation of the incidence of this unusual situation must not affect the decision to control severe pain.[609] It is very unfortunate that subtle misconceptions interfere with providing appropriate pain relief. In one study, standardized patients with a chief complaint of pain who gave histories of frequent pain crises were given less opioid by nurses than the identical patients whose scripts included a history of infrequent pain episodes.[610]

Reduction in Polymer Formation

Pharmacologic Induction of Hemoglobin F

Increasing the amount of HbF will decrease the intracellular concentration of HbS and increase the delay time and solubility of HbS, which slows polymer formation and sickling. On the basis of epidemiologic data that showed that increases in HbF from 4% to 16% could decrease vaso-occlusive crises by 50%,[152] as well as numerous CSSCD studies that showed HbF to be the single most predictive factor of clinical severity and even survival, one therapeutic approach given considerable effort over the last 30 years has been the pharmacologic induction of HbF beyond the fetal and newborn period. Several pharmacologic agents have shown promise including demethylating agents such as 5-azacytidine[611] and decitabine,[612-614] and short-chain fatty acids such as butyrate,[615-618] but each has limitations in route of administration, safety, or sustained efficacy. Hydroxyurea, first introduced by Platt and co-workers,[619] has emerged as the single therapeutic agent to gain Food and Drug Administration (FDA) approval for the treatment of SCA, although it is approved only for adults with severe disease.

Hydroxyurea may be an ideal therapeutic agent for use in children with SCA. It has excellent bioavailability after oral administration; requires only once-daily dosing, which improves medication adherence; has few if any immediate side-effects; has predictable hematologic toxicities that are dose-dependent, transient, and reversible; and has sustained benefits against multiple pathophysiologic mechanisms of SCA, including potent HbF induction.

In patients with hemoglobinopathies, the myelosuppressive and cytotoxic effects of hydroxyurea appear to alter erythroid kinetics by inducing erythroid regeneration and the premature commitment of erythroid precursors, with resulting increased production of HbF-containing reticulocytes (F-retics) and total HbF.[620] Additional pharmacologic effects of hydroxyurea that may contribute to its beneficial effects in SCA include increasing erythrocyte HbF through NO-dependent pathways, decreasing the neutrophil count, increasing erythrocyte volume and hydration, increasing deformability of sickle erythrocytes, and altering the adhesion of sickle erythrocytes to the endothelium.[619-623] The potential release of NO directly from the hydroxyurea molecule[624,625] could also provide beneficial local effects on the endothelium, thereby ameliorating the vaso-occlusive process and limiting vascular dysfunction.

Pilot trials in patients with SCA demonstrated that hydroxyurea increased HbF and caused little short-term toxicity.[619-622] In addition to increasing HbF, hydroxyurea was noted to reduce the proportion of dense cells and increase the MCV and MCHC of sickle cells.[619-621,626] On the basis of these favorable results, the NHLBI sponsored the pivotal Multicenter Study of Hydroxyurea (MSH) in adults with SCA.[243] This trial was terminated early when it was obvious that vaso-occlusive crises, ACS, transfusions, and hospitalizations were reduced by almost 50% in the hydroxyurea-treated group compared with controls. However increases in HbF alone did not predict the decrease in painful crises seen in this double-blinded placebo-controlled randomized trial.[243] Multiple factors such as perturbation of WBC or cytokine levels, changes in RBC adhesion to vascular endothelium (see Fig. 20-1), or alteration of NO/intravascular Hb equilibrium may also play a role in hydroxyurea-related decrease in crises.[627,628]

A 9-year follow-up observation of adult MSH subjects taking hydroxyurea revealed an impressive 40% reduction in mortality,[629] and a subsequent assessment after 17.5 years of follow-up study revealed that hydroxyurea continued to be associated with improved survival and without accompanying serious adverse events.[630] In 2008 an NIH Consensus Development Conference was commissioned and performed a systematic review of the efficacy, effectiveness, toxicity, and barriers to the use of hydroxyurea in SCD. The conclusion was, "Strong evidence supports the efficacy of hydroxyurea in adults to decrease severe painful episodes, hospitalizations, number of blood transfusions, and the ACS. Although the evidence for efficacy of hydroxyurea treatment for children is not as strong, the emerging data are encouraging."[631]

After small-scale trials of hydroxyurea therapy in children demonstrated that the drug could be given safely,[296,632,633] the first pediatric multicenter phase I/II trial of SCA (HUG-KIDS)[634] revealed similar hematologic effects as seen in the MSH trial with improved anemia (increased Hb and decreased reticulocytosis) as well as diminished hemolysis (decreased LDH and decreased total bilirubin), macrocytosis, improved erythrocyte hydration, and striking increases in %HbF and F cells. Laboratory toxicities were mild and reversible with no life-threatening clinical events observed. Subsequent evaluation of the HUG-KIDS cohort revealed no adverse effects on growth or pubertal development,[635] and predictors of HbF response included compliance and higher baseline HbF, as well as higher Hb, WBC, and reticulocytes that allowed a higher MTD.[636] Five- and 10-year follow-up studies of hydroxyurea in children with SCA continue to demonstrate increased HbF with minimal side effects and improved growth parameters.[637] It is important to note that in the only large study of 122 children in which MTDs were obtained in the same fashion as in the adult MSH study, very few if any nonresponders were noted. Hydroxyurea therapy at MTD is well tolerated and demonstrates sustained hematologic efficacy with apparent long-term safety.[638]

The efficacy of hydroxyurea to prevent acute complications of SCA in infants as young as 9 months old has recently been evaluated; BABY HUG was the phase III multicenter double-blinded placebo-controlled randomized trial of hydroxyurea in infants as young as 9 months. This study demonstrated the efficacy of hydroxyurea to reduce the rate of acute complications including pain and dactylitis, with additional evidence for decreased hospitalizations, transfusions and ACS, while also demonstrating safety with no increased risk of infection or serious adverse events.[244]

The role of hydroxyurea in preserving organ function in SCA has not yet been determined. From a practical standpoint, these beneficial effects are difficult to assess prospectively because organ damage develops broadly over the whole pediatric age range, beginning with splenic and renal changes in infancy and evolving to pulmonary and neurologic deficits with vasculopathy among older children. In the open-label Hydroxyurea Safety and Organ Toxicity (HUSOFT) study, SCA infants had preserved splenic filtrative function compared with historic controls,[639] and a follow-up study on this cohort identified preservation and even apparent gain of function in some cases.[393] Similar beneficial effects of hydroxyurea on organ function have now been reported anecdotally, usually single-institution experiences for children with proteinuria,[486] priapism,[342,351] hypoxemia,[640] PHT,[641] glomerular hyperfiltration,[642] neurocognitive delay,[643] elevated TCD velocities,[644] primary stroke prevention,[644,645] and secondary stroke prevention.[297] Based on these encouraging but uncontrolled reports, several prospective multicenter randomized trials using hydroxyurea to prevent organ dysfunction in SCA are currently under investigation. Practical guides to initiation and monitoring of hydroxyurea therapy in children have been published,[646,647,648] and the upcoming NHLBI guidelines have strongly worded recommendations about offering hydroxyurea to all young patients with SCA.

Decreased Cell Hemoglobin S Concentration

Because the polymerization of HbS is exquisitely concentration dependent, reduction of MCHC by swelling the cell with water has been considered as a therapeutic maneuver. Two approaches have been tried: lowering plasma osmolarity and increasing intracellular cations. The first approach was used by Rosa and colleagues,[649] who successfully reduced the duration and frequency of painful crises by lowering the MCHC using dietary salt restriction and desmopressin. Subsequently others have found this therapy too difficult to maintain, neurologically toxic, and ineffective.[650-652] The second approach focused on the property of various membrane-active agents to increase intracellular cations. Some of the interesting agents include the antibiotics monensin[653] and gramicidin[654]; calcium channel blockers nitrendipine, nifedipine, and verapamil[655]; and the peripheral vasodilator cetiedil,[656] but none has reached clinical trial. As discussed previously, preliminary evidence suggests that blocking the Gardos channel with clotrimazole[657] and blocking K^+,Cl^- cotransport with oral magnesium[658] may decrease HbS concentrations by preventing erythrocyte dehydration. Only the Gardos channel inhibitor senicapoc entered formal clinical trials, and although it demonstrated substantial effects on erythrocyte hydration,[90] the definitive phase III trial demonstrated no efficacy for reducing vaso-occlusive events.[91]

Increased Hemoglobin S Solubility

The most straightforward approach to preventing the polymerization of HbS is to attack the $\beta^{6\ \text{valine}}$ that is the key to polymer formation. Unfortunately this is an extremely unreactive residue, so efforts to increase the solubility of HbS have hinged on the importance of the other intermolecular contacts. Reagents that increase deoxy-HbS solubility by noncovalent interactions with HbS have been recognized. Chang and colleagues[654] compared the effects of 15 antisickling agents on HbS solubility, oxygen affinity, and cell sickling. Urea is an effective agent but requires concentrations greater than 200 μM, too high for in vivo use. The best studied covalent modifier is cyanate, but clinical trials have not been promising. Unfortunately despite the encouraging clinical and in vitro data, this compound is not usable because of significant neurotoxicity[659] and cataract formation.[660] A major problem with covalent reagents is that they interact with a wide variety of functional groups found in many molecules other than Hb.

Decreased Dwell Time

Any manipulation that would allow a cell to traverse a vessel faster than its delay time will prevent occlusion of that vessel. Therapies aimed at reducing endothelial adherence have only recently been successful. Attempts to develop a vascular lubricant include purified poloxamer 188, a nonionic block copolymer that improves micrvascular blood flow by reducing viscosity and adhesive frictional forces.[661] This has led to an ongoing phase III study of poloxamer 188 to reduce the duration of vaso-occlusive crisis in SCD.[662] Recognition of the role of leukocyte adhesion to the vascular endothelium in the process of vaso-occlusion led to promising investigations of selectin blockade with synthetic glycomimetic molecule[663] and monoclonal antibody[135] in murine models. These have led to initiation of phase II multicenter, randomized, placebo-controlled trials for the treatment/prevention of vaso-occlusive pain.[664-666] Rodgers and co-workers[667] showed that microcirculatory flow in patients with SCD has an unusual periodic pattern, indicating abnormal vasomotor control. Recent work indicates that free plasma HbS binds NO, thus reducing NO availability to maintain vasodilation[125,668] and could lead to increased vasocontriction and dwell time (see Fig. 20-1). Efforts to increase NO bioavailability with use of inhaled NO in a prospective, multicenter, double-blind, randomized, placebo-controlled clinical trial did not improve the time to crisis resolution.[669] Intravascular hemolysis also consumes arginine, the obligate substrate for NO production, thereby contributing to decreased NO bioavailability.[670]

Transfusion

Transfusions improve oxygen-carrying capacity, alleviate anemia, and decrease the proportion of erythrocytes that carry HbS. Although transfusion is typically not used for the treatment of chronic anemia or acute painful crises, it is often necessary for associated comorbidities.[671] Current transfusion practices include episodic or chronic regimens depending on whether the risk reduction for severe clinicopathologic sequelae from SCD (e.g., stroke or recurrent ACS) outweighs the risks inherent to a chronic transfusion regimen.

Episodic transfusions (simple or exchange) are used primarily to treat acute complications of SCD. Simple transfusion is possible when the anticipated posttransfusion Hb will not exceed 10 to 11 g/dL. Sickle trait blood should not be used because of difficulties in monitoring the response by electrophoresis. Exchange transfusion (either by manual technique or automated erythrocytapheresis) is reserved for complications that are either life-threatening or pose risk for irreversible tissue damage (e.g., stroke or severe ACS) or when initial simple transfusion was ineffective. The primary goal of exchange transfusion is to reduce the HbS concentration rapidly to less than 30% of the total Hb content without increasing blood viscosity or expanding the blood volume, thereby reducing potential cardiovascular strain. In those centers in which an automated cell separator is available, a two-volume exchange transfusion can be efficiently accomplished in less than 90 minutes.[347,348] Episodic simple transfusion is indicated for the management of symptomatic episodes of acute anemia (e.g., aplastic crisis triggered by parvovirus infection), severe/progressive ACS, acute stroke, splenic sequestration, priapism unresponsive to medical therapy, and perioperatively.

Chronic transfusion therapy is implemented when the ongoing risk of morbidity from SC complications outweighs the risks inherent to recurrent blood exposure. In a chronic regimen, transfusions are usually scheduled every 4 weeks and use simple or exchange methods with the goal of maintaining the HbS level lower than 30%. Chronic transfusion therapy has been indicated for primary stroke prevention in children identified by abnormal TCD velocity (>200 cm/s) and for secondary stroke prevention in children who have already experienced an overt stroke. Limited duration regular transfusions may be indicated for reducing the frequency and severity of ACS, complicated pregnancy, prolonged hematuria, and chronic vaso-occlusive complications (e.g. nonhealing leg ulcer). Routine pain is not an indication for chronic transfusion therapy.

Chronic transfusion regimens in SCD may increase the risk of transfusion-associated complications of allosensitization, infection, and progressive iron overload. Transfusional iron accumulation is unavoidable, because there is no physiologic mechanism for iron removal. Excess iron is deposited in multiple organs including the liver, heart, pancreas, endocrine glands, and skin, with potential for organ damage, and can go clinically undetected and undertreated if not anticipated. Fortunately iron chelators including parenteral deferoxamine,[672,673] oral deferasirox,[674] and oral deferiprone are available and effective if adhered to as prescribed. Serial assessment of serum ferritin levels may provide insight into ongoing iron balance in SCD[675,676]; however, because infections and vaso-occlusive crises also increase ferritin levels, it is an inaccurate predictor of liver iron burden. MRI estimation of hepatic iron has largely replaced liver biopsy for hepatic iron quantification. MRI has the additional benefit of noninvasively quantifying extrahepatic iron, particularly cardiac iron in transfusional hemosiderosis.[677] The pathophysiology of tissue iron loading in chronically transfused patients with SCD appears to be different than in other transfusion-dependent anemias such as thalassemia; specifically cardiac and endocrine iron loading are not as common in SCD,[678,679] and high levels of liver iron were not associated with as much liver disease compared with similar levels in thalassemia.[680]

The incidence of erythrocyte alloimmunization in the general U.S. population has been estimated to be approximately 0.5% to 1.5%. In contrast the incidence of alloimmunization in patients with SCD ranges from 18% to 76% with ABO and D matching alone; 5% to 14.5% with limited phenotype matching for C, E, and K antigens; and 7% for extended minor RBC antigen-matching beyond C, E, and K.[681-683] The likelihood of alloimmunization is related to the number of transfusions, the racial differences between common donor and recipient erythrocyte phenotype, possibly the age of the recipient, and as yet unknown genetic factors that control the responsiveness of the recipient to transfused antigens.[292,684] Opinions and practices differ regarding the utility of preventing sensitization using antigen-matched cells in all recipients, in contrast to only providing matched cells after sensitization occurs.[685,686] The most common antibody-provoking antigens are C, E, K, Jk^b S, Fy^a, and Fy^b.[684] Ideally patients with SCD should receive antigen-matched red cells beyond ABO and D to include C, E, and K to reduce the hazard of sensitization,[686] and such a strategy has been demonstrated prospectively to reduce sensitization.[687] Some suggest further extension of phenotype matching,[688,689] but the added expense and relative scarcity of the required random donors makes this impractical.[686] Despite C, E, and K matching, many patients with SCD continue to form alloantibodies with common Rh specificities (D, C, E, c, e). Some cases can be blamed on transfusion at outside institutions without extended crossmatching,[683] whereas others have observed higher-than-expected rates of allosensitization despite matching donors with C, E, K, and ethnicity because of unusually diverse Rh system variants revealed by genotyping.[690]

Potential benefits from attempting to prevent allosensitization include prevention of complications from the first delayed transfusion reaction and possibly the prevention of autoantibodies that appear in the same context. Clinically significant autoantibodies do occur in about 10% of patients with SCD, and the incidence appears to be higher in those with alloantibodies.[684,689,691] In 183 children the incidence of autoantibodies was 7.6% ,and when associated with C3 on the red cells, resulted in hemolysis.[293] However many patients with SCD who develop apparent autoantibodies to their Rh antigens using routine serologic reagents may actually have developed Rh alloantibodies, because they harbor RH gene variants detectable by genotyping.[692]

Hematopoietic Stem Cell Transplantation

The only current curative approach to SCD is hematopoietic stem cell transplantation (HSCT). HSCT from sickle trait or normal human leukocyte antigen (HLA)-identical siblings with have been performed in over 250 young patients.[693,694] Preparative regimens have been primarily myeloablative (e.g., busulfan and cyclophosphamide) and involve a spectrum of graft-versus-host disease (GVHD) prophylaxis including antithymocyte globulin, cyclosporine, corticosteroids, irradiation, and methotrexate. HLA-identical sibling HSCT for SCD has a reported overall survival of 93% to 97%, event free survival of 82% to 85%, and rejection/recurrence of SCDs of about 10%.[695] More recently among 87 consecutive patients treated with myeloablative regimens, addition of antithymogyle globulin reduced rejection from 23% to 3%.[696]

Transplant complications have included CNS hemorrhage (particularly in patients with history of stroke), hypogonadal function, graft rejection, and acute or chronic GVHD.[693,696-698] Prophylactic anticonvulsant treatment and maintenance of a high platelet count may result in reduced CNS morbidity.

In patients who have stable donor engraftment, complications related to SCD resolve, and there are no further episodes of pain, stroke, ACS, or sickle-related CNS complications. Stabilization or reversal of SCD-related organ damage has been documented after HSCT.[547] There is evidence of stabilization of CNS disease by MRI,[696] but reversal of cerebral vasculopathy has been variable.[699,700] Improvements in other end-organ function has been observed, including radiologic improvement of AVN of the humeral head[701] and return of splenic phagocytic function.[702] In a recent summary of 53 children with SCA undergoing bone marrow transplant, growth was not impaired in younger children, but diminished growth occurred in patients who received transplants near or during an adolescent growth spurt.[703]

Although HSCT offers the potential for cure, barriers to its wider adoption include relative paucity of HLA-identical sibling donors, eligibility restrictions, and the high risks of regimen-related infertility as well as lower risks of GVHD, mortality, and secondary malignancy. Several novel approaches to improve the safety and availability of HSCT aim to decrease the associated toxicity and expand the pool of potential donors. These approaches include nonmyeloablative or reduced-intensity conditioning regimens[704,705] and the use of haplo-identical[706-708] and HLA-matched unrelated donors.[325]

Gene Therapy

The most direct approach to a cure for SCD may lie in the correction or replacement of the patient's own defective β-globin gene with a normal gene. Genetically engineering autologous hematopoietic stem cells offers two major benefits over HSCT: these stem cells eliminate the need to find a HSCT donor and eliminate the risks of GVHD and immune-mediated graft rejection.

Gene therapy for the β-hemoglobinopathies has been explored as a promising avenue in multiple preclinical and a few clinical studies. The design of integrative vectors for human β-globin gene transfer has been difficult. The genetic elements required for high erythroid specific expression include the β-globin gene with its introns, promoter, and β-locus control region (β-LCR). However murine models of β-thalassemia and SCD have been corrected by using lentiviral vectors encoding either a human γ-globin gene[709] or a normal or modified β-globin gene designed for antisickling activity.[710-712] An ongoing clinical trial in France for patients with SCD or β-thalassemia has reported its first successful case in which the lentiviral vector encodes a modified β-globin with antisickling properties.[713]

Rather than relying on the random insertion of a normal β-globin gene and the potential for insertional mutagenesis and malignant transformation, taking advantage of genomic editing tools is another avenue of onging investigation. Transplantation of embryonic stem cells or induced pluripotent stem cells from donor fibroblasts after homologous recombination replaced the human β^S gene with a normal human β-globin gene has led to the correction of the sickle mutation in transgenic mice.[714,715] The advent of even more precise and specific genomic editing tools such as zinc-finger nucleases (ZFNs), transcription activator-like effector nucleases (TALENs), and clustered regulatory interspaced short palindromic repeat (CRISPR)/Cas-based ribonucleic acid (RNA)-guided DNA endonucleases[716] may allow for even more precise correction of the DNA base pairs underlying the sickle mutation.

In contrast to other gene therapy strategies involving the insertion of a normal γ or β globin that requires expression of the transgene to compete with and exceed the endogenous mutant β^S-globin production, another approach under consideration would not alter the β-globin locus but rather take advantage of the normal regulatory machinery that controls the γ-to-β–globin switch that occurs in hematopoietic development. This could be accomplished by delivery of a short-hairpin (sh) RNA-targeting knock-down of BCL11A[164] or genomic editing/disruption of the known intronic *BCL11A* enhancer elements[717] in hematopoietic stem cells. The reduction of BCL11A would result in concurrent increased γ-globin and reduced mutant β^S globin expression and the potential for greater clinical impact by simultaneously harnessing the antisickling effects of HbF and silencing the mutated β^S-globin.

Preparation for Surgery

Children with SCD have increased likelihood of undergoing surgical procedures, in particular cholecystectomy, splenectomy, tonsillectomy/adenoidectomy, and joint replacement. The CSSCD found that 7% of all deaths among patients with SCD were related to surgery.[131] In 1079 surgical procedures on 717 patients of all genotypes the mortality within 30 days of the procedure was 1.1% (12 deaths); however no deaths were reported in children under 14 years of age.[718] That same series illustrated comparable complication rates among SCD genotypes and suggested that patients undergoing regional anesthesia were at higher risk of complications than those undergoing general anesthesia.[718]

The CSSCD "natural history" study did not definitively address the important question of the effectiveness of preoperative transfusion. In a review of records from Dallas Children's Hospital, pulmonary complications were particularly common among patients undergoing laparotomy, thoracotomy, or tonsillectomy and adenoidectomy who did not receive preoperative transfusions (9/29), compared with those who did receive transfusions for those procedures (0/8).[719] Vichinsky and collaborators in the Preoperative Transfusion in Sickle Cell Disease Study Group reported the findings of a prospective, multi-institutional study that randomized over 600 patients with HbSS to preoperatively receive either simple transfusion designed to increase the total Hb to 10 g/dL or exchange transfusion designed to decrease HbS% to less than 30 and increase total Hb to 10 g/dL.[720-724] Several key points emerged from that study:

- There was no significant difference between the two transfusion strategies in terms of complications; however, both strategies reported a high 30% to 35% postoperative complication rate.
- Transfusion-related complications were twice as common (14%) in the exchange transfusion arm, compared with the simple transfusion arm (7%).
- The most common and serious complication was ACS, which occurred in 10% of procedures in both arms. The average time at onset was postoperative day 3; the average length of episode was 8 days; 11% of the patients required intubation, and two died.
- Those with higher surgical risk category, history of pulmonary disease, incidence of ACS, and frequency of hospitalization were at higher risk of complications.

These data suggest that at least a simple transfusion designed to raise the preoperative Hb to 10 g/dL should be given to all patients with SCD before surgery.

The multicenter, unblinded randomized Transfusion Alternatives Preoperatively in SCD (TAPS) trial compared the outcomes of preoperative transfusion versus no preoperative transfusion in patients with SCA undergoing low-risk or medium-risk surgery.[725] The study was terminated prematurely because there was a significantly lower rate of perioperative complications in the transfused group (5/34, 15%) than the untransfused group (13/33, 39%). Two major questions remain: what is the best preoperative management for low-risk procedures, and what is the best preoperative management for patients with Hb too high for simple transfusion (e.g., HbSC or S β^+-thalassemia)?

In addition to transfusion, perioperative morbidity can be minimized safely by careful collaboration between hematologist, anesthesiologist, and surgeon during the perioperative period. Those with prior pulmonary dysfunction, ACS, or history of multiple hospital admissions should receive a minimum of overnight maintenance IV hydration and be monitored perioperatively as high-risk patients. During the procedure and in the postoperative period all patients should have compulsive attention paid to oxygenation, ventilation to prevent atelectasis, hydration, maintenance of warm body temperature, acid-base balance, and positioning that does not impair circulation.[718,726-731] Choice of an anesthetic agent is not as critical as the care with which it is delivered.[728]

OTHER SICKLE SYNDROMES

Sickle Cell Trait ($\alpha_2\beta_2$, $\alpha_2\beta_2^{6\ \text{Val}}$)

Sickle cell trait is the term describing individuals who are heterozygous carriers for the HbS mutation. Sickle cell trait is estimated to affect up to 3 million Americans and hundreds of millions of persons worldwide[732] but is generally not associated with increased morbidity or mortality under normal physiologic conditions.[733-737] There is no associated anemia, abnormal erythrocyte morphology, or decreased red cell survival. Most individuals have approximately 40% HbS and 60% HbA; however, comorbid α-thalassemia can reduce the HbS fraction to 28% to 35%.[738] Decreased levels of HbS can also be seen in patients with comorbid iron[739] and folate[740] deficiencies. Growth, behavior, and educational achievement and pregnancy risks in children with sickle trait are entirely normal.[741-743] Patients diagnosed with sickle trait but developing a clinical and laboratory phenotype consistent with a significant sickling phenotype should be considered for molecular globin diagnostics to assure accuracy of diagnosis.[744,745]

Under certain extreme conditions, however, sickling and even death may occur in individuals with sickle cell trait. These include severe pneumonia,[746] unpressurized flying, and exercise at high altitudes.[747,748] The risk of sickle trait in routine commercial aviation has been overstated.[749] Sickle cell trait has been associated with medical complications[750] including loss of urinary concentrating ability (hyposthenuria),[751] papillary necrosis with persistent hematuria,[452] and rarely renal medullary carcinoma.[469] Sickle cell trait may be a risk factor for end-stage renal disease; however, data is conflicting.[750,752,753] Under extreme conditions such as high altitudes, severe left upper quadrant pain associated splenic infarction can occur.[754] Sickle cell trait has been associated with increased risk of venous thromboembolism.[755] Women with sickle trait have shown an increased risk for preeclampsia; however, their infants showed a minimal decrease in gestational age and birth weight and no increased infant mortality.[756] Traumatic hyphema in sickle trait is a medical emergency, because in the hypoxic conditions of the anterior chamber of the eye HbAS erythrocytes sickle with mechanical obstruction of aqueous humor outflow and development of increased intraocular pressure.[757,758] Careful general anesthesia does not carry a great risk for the individual with sickle trait,[759,760] but tourniquet surgery[728] and deep hypothermia should be avoided.

In a retrospective study of basic training in the U.S. Armed Forces, Kark and colleagues noted a 27 times greater relative risk of sudden unexplained death among recruits with sickle cell trait compared to non-HbS controls.[761] Deaths were associated with exertional heat stress, heat stroke, and rhabdomyolysis in the context of previously poorly conditioned individuals undergoing strenuous physical exertion. After this report universal modifications in basic training drill schedule and improved attention to hydration status improved the rate of sickle cell trait-related sudden death.[762,763] When exertional death was examined in National Collegiate Athletic Association (NCAA) Division I football players, the relative risk of death was 22 times greater in athletes with sickle cell trait compared with those without SCT, and all 5 deaths of patients observed to have SCT occurred during practice and conditioning drills.[764] In 2010 as the result of a lawsuit settlement, the NCAA adopted a policy requiring Division I student athletes to be screened for sickle cell trait, and this has subsequently been extended to Divisions II and III. The American Society of Hematology does not support the screening for sickle cell trait as a prerequisite for athletic participation.[765]

Hemoglobin SC Disease ($\alpha_2\beta_2^{6\ \text{Val}}$, $\alpha_2\beta_2^{6\ \text{Lys}}$)

HbSC disease is a milder chronic hemolytic anemia than SCA and is associated with variable degrees of vaso-occlusive complications. As described in Table 20-1, the patient typically has an Hb concentration of 10 to 12 g/dL, a reticulocyte count of 1% to 13%, and a relative microcytosis for the degree of reticulocytosis. The peripheral blood smear (see Fig. 20-5) is more characteristic of HbC than of HbS, showing impressive target cells, microcytosis, and rarely, ISCs. The clinical course of HbSC is quite variable, with some patients severely affected at an early age and others entirely asymptomatic and identified only as adults on routine screening. Hemolysis is less severe than SCA,[766] resulting in a higher hematocrit level with resulting higher blood viscosity.

The major complications of SCA are not as common in HbSC disease, but all have been reported including recurrent painful bone crises, painful abdominal crises, gallstones, pulmonary infarction, priapism, and CNS infarction.[767-770] As shown in Figure 20-6, the pattern of clinical events is different in HbSC, with most events occurring not only less often but later in life. Certain complications appear to be common and perhaps reflect higher blood viscosity including eye disease,[505,768,771-773] AVN of the femoral heads, renal papillary necrosis,[774] and pregnancy-related problems.[775] Splenomegaly is found in approximately 60% of patients with HbSC disease and has been associated with late-onset splenic infarction[776] and splenic sequestration,[777] particularly at high altitudes. Although infection is not as common as in SCA,[778] splenic hypofunction and an increased risk of pneumococcal and *H. influenzae* sepsis are observed.[779] For this reason, pneumococcal and *H. influenzae* vaccines are indicated, and the use of prophylactic penicillin is recommended for children with HbSC.

The utility of hydroxyurea for patients with HbSC has not been well studied, with only small series and little prospective research. Favorable hematologic and clinical results have been reported,[780,781] but the only prospective trial was terminated because of poor enrollment and so provided few meaningful results.[782] A robust clinical trial using hydroxyurea for HbSC is sorely needed and was identified as an important knowledge gap in the most recent NHLBI SCD guidelines.

Patients with HbSC disease clearly have more sickling complications than individuals with sickle trait, who are essentially free of sickling complications. One would therefore assume that mixtures of HbS and HbA are less likely to polymerize than mixtures of HbS and HbC. Interestingly Bunn and associates[783] have shown that this is not the case, because the kinetic and equilibrium behaviors of mixtures HbS and HbA are essentially identical with the behaviors of mixtures of HbS and HbC. One can resolve this apparent paradox by considering how the Hb mixtures are packaged in SC and AS cells. Two major factors explain why HbSC cells sickle more readily than AS cells: 1) There is more HbS in an HbSC cell, and 2) there is a higher MCHC in an HbSC cell. Because the charge and affinity for β globin differs between β^S globin and β^C globin, individuals with HbSC disease usually have 50% HbS and 50% HbC, whereas those with the sickle trait typically have 60% HbA and 40% HbS.[784] This increased HbS content of SC cells results in an approximately sevenfold increase in the rate of polymerization.[784] The increase in MCHC in HbSC disease, which is quite obvious on density separation of HbSC red cells[783,785,786] (see Fig. 20-5) and even C-trait red cells,[784] is probably the result of the activation by the positively charged HbC molecules of the K^+,Cl^- cotransport system.[787] The cellular dehydration and microcytosis associated with HbC has been well characterized by Brugnara and colleagues[788] and Ballas and associates.[786]

Hemoglobin S β-Thalassemia

Patients heterozygous for HbS and β-thalassemia have clinical severity that depends on the output of the thalassemic β gene.[357,789,790] If no HbA is produced (S β^0-thalassemia), the clinical course is comparable (see Table 20-1) with that of homozygous HbSS; hence both are referred to as SCA. The Hb electrophoresis shows mostly HbS and variable amounts of HbF. These patients are more often of Mediterranean or Middle Eastern origin, have microcytosis, and often have palpable splenomegaly. One parent will have classic sickle trait, whereas the other will have β-thalassemia trait with eleveated HbA_2. Peripheral blood morphology is notable for target cells and microcytosis.

If there is output from the thalassemic β-globin gene (S β^+-thalassemia), patients tend to have a milder clinical course, comparable with that of HbSC disease. The Hb electrophoresis shows predominantly HbS and variable amounts of HbF and HbA. Most African Americans with HbS β^+-thalassemia will have about 15% to 20% HbA, which is enough to modify the clinical course but not enough to abrogate the pathophysiology. The features that distinguish these individuals from those with SCA are the presence of HbA, microcytosis, splenomegaly, and a relatively benign clinical course. The ameliorative effects of HbA (see Table 20-1) are apparent. These patients can be distinguished from individuals with sickle trait, because HbS percentage is greater than that of HbA, as well as microcytosis, hemolytic anemia, abnormal peripheral morphology, and splenomegaly.

Hemoglobin SO_{Arab} ($\alpha_2\beta_2^{6\ Val}$, $\alpha_2\beta_2^{121\ Lys}$)

$HbSO_{Arab}$ compound heterozygotes are quite rare and have a severe sickling phenotype with chronic hemolytic anemia and vaso-occlusive episodes.[791,792] The O_{Arab} β-globin mutation lies within the area critical to the axial contact in the HbS fiber. Routine cellulose acetate electrophoresis at pH 8.6 does not distinguish between HbC and HbO_{Arab}. Citrate agar electrophoresis at pH 6 does separate HbC from HbO_{Arab} and should be done on patients who appear to have HbSC disease on cellulose acetate electrophoresis but who have particularly severe symptoms.[793] The peripheral blood smear typically shows sickled erythrocytes and target cells with polychromasia and nucleated RBCs.

Hemoglobin SD Disease ($\alpha_2\beta_2^{6\ Val}$, $\alpha_2\beta_2^{121\ Glu}$)

HbSD compound heterozygotes have a severe hemolytic anemia with a peripheral blood smear comparable to that seen in SCA. These rare patients have severe vaso-occlusive complications,[794-796] illustrating as those with the HbO_{Arab}, the critical nature of the β^{121} contact site. HbD migrates with HbS on cellulose acetate electrophoresis at alkaline pH but can be distinguished on citrate agar electrophoresis at acid pH. HbD should be suspected when an Hb appears to be HbS on cellulose acetate electrophoresis but gives a negative “sickle prep.” The HbD mutation has been identified worldwide but most commonly occurs in India, so the variant is often called HbD_{Punjab}.

Hemoglobin S Korle Bu ($\alpha_2\beta_2^{6\ Val}$, $\alpha_2\beta_2^{73\ Asn}$)

Hb Korle Bu is a rare Hb mutant.[797] It is mentioned here only because it illustrates an important pathophysiologic point. Korle Bu participates poorly in sickling.[798] This mutation interferes with the lateral contact between HbS fibers by blocking the critical receptor area for the Val-β6. S Korle Bu compound heterozygotes are entirely free of symptoms.

Hemoglobin C_{Harlem} ($C_{Georgetown}$) ($\alpha_2\beta_2^{6\ Val,\ 73\ Asn}$)

Hb C_{Harlem} (also known as $C_{Georgetown}$) has two substitutions on the same β chain: the sickle mutation $\beta^{6\ Val}$ and the Korle Bu mutation $\beta^{73\ Asn}$.[799] Patients with these mutations are asymptomatic. Patients doubly heterozygous for HbS and HbC_{Harlem} have clinical crises resembling SCA.[799,800]

Hemoglobin S Antilles ($\alpha_2\beta_2^{6\ Val,23\ Ile}$)

HbS Antilles also has two substitutions on the same β chain: the sickle mutation $\beta^{6\ Val}$ and a second mutation, $\beta^{23\ Ile}$.[801] This mutation results in a low–oxygen-affinity Hb that in heterozygotes for HbA and HbS Antilles results in a mild hemolytic anemia and the presence of 5% to 7% irreversible sickled cells. A transgenic mouse with HbS Antilles and the HbD (see earlier) mutation exhibits many of the clinical features of SCA.[802]

Hemoglobin S Québec-CHORI ($\alpha_2\beta_2^{6\ Val}$, $\alpha_2\beta_2^{87\ Ile}$)

Hb Québec-CHORI is an electrophoretically silent Hb variant that is indistinguishable from HbA by standard clinical electrophoresis and therefore if in compound heterozygous state with the sickle mutation may present with a newborn screen “FAS” phenotype mimicking sickle trait. Hb Québec-CHORI readily separates by

HPLC. Two cases of compound heterozygous Hb S Québec-CHORI have been reported in the literature.[803,804] Functional studies have revealed that Hb S Québec-CHORI behaves similarly to HbS with respect to nucleation and polymerization,[803] which accounts for the sickle phenotype in the two affected patients. One of the cases had a favorable response to hydroxyurea.[745]

Hemoglobin SE ($\alpha_2\beta_2^{6\ \mathrm{Val}}$, $\alpha_2\beta_2^{26\ \mathrm{Lys}}$)

HbE is found primarily in Sri Lanka, India, and Southeast Asia. Patients homozygous for HbE have a mild anemia and microcytosis and are clinically asymptomatic; however, compound heterozygotes for HbE and a β-thalassemia mutation have variable phenotype from mild to severe, with some virtually indistinguishable from β-thalassemia major.[805] The HbE mutation creates a cryptic splice site and therefore manifests also as a mild β^+-thalassemia mutation.[806] The clinical phenotype of HbSE disease appears to be relatively mild, resembling that of HbSβ^+-thalassemia; however vaso-occlusive crises, ACS, splenic sequestration, rhabdomyolysis, and AVN have been described.[807-809] HbSE will be diagnosed more often while population migration patterns change and racial intermarriages become more prevalent. HbSE may be initially misdiagnosed because of the comigration of HbE with other Hbs under some screening conditions. The Hb ratio is usually 60% to 65% HbS and 30% to 35% HbE. Affected individuals are mildly anemic with microcytosis (MCV 65-75fL).

Hemoglobin C Disease ($\alpha_2\beta_2^{6\ \mathrm{Lys}}$, $\alpha_2\beta_2^{6\ \mathrm{Lys}}$)

Homozygous HbC disease is a mild disorder characterized by hemolytic anemia, microcytosis, and splenomegaly.[810-812] The tendency of HbC to aggregate and crystallize[813-815] is probably responsible for the characteristic target morphology of the stained and dried red cell in homozygous C disease and in HbC trait, although these crystals are not likely to be directly responsible for the hemolytic anemia. In HbC trait, target cell formation and mild microcytosis is the only manifestation of the anomaly. Most patients are identified on newborn screening; the diagnosis should be confirmed, families given proper genetic counseling, education about how HbC disease is not a form of SCD, and that the hemolytic anemia is very mild.[812]

Mild β-Thalassemia
Severe β-Thalassemia
Interaction of Thalassemia with Globin Structural Variants
PRENATAL DIAGNOSIS OF THALASSEMIA

The thalassemias are a heterogeneous group of inherited forms of anemia caused by mutations that affect the synthesis of hemoglobin.[1-3] Milder forms are among the most common genetic disorders, whereas the severe forms, which are seen less often, lead to significant morbidity and mortality worldwide (Fig. 21-1).

Study of the thalassemias traces the history of the application of recombinant deoxyribonucleic acid (DNA) methods to analysis of inherited diseases and underscores how naturally occurring mutations in humans illuminate genetic principles. In this chapter the genetics of hemoglobin genes are reviewed as background for discussion of the molecular basis of the thalassemia syndromes, their clinical phenotypes, current management, and prenatal diagnosis.

HUMAN HEMOGLOBINS: COMPOSITION AND GENETICS

Normal hemoglobins are tetramers of two α-like and two β-like globin polypeptides. The predominant hemoglobin in normal adult red blood cells is hemoglobin A (HbA), $\alpha_2\beta_2$.[4,5] The α- and β-globins contain 141 and 146 amino acids, respectively. In addition to HbA, adult red blood cells normally contain two minor hemoglobins: HbA_2 ($\alpha_2\delta_2$) and fetal hemoglobin (HbF) ($\alpha_2\gamma_2$). The γ and δ polypeptides are related to β but differ in their primary amino acid sequences; hence they are referred to as β-like globins. HbA_2 normally accounts for 2% to 3.5% of the total hemoglobin. Although it is a minor component in adult red blood cells, HbF is the predominant hemoglobin in fetal red blood cells during the latter two trimesters of gestation. Because it does not bind 2,3-diphosphoglycerate, its affinity for oxygen is higher than that of HbA.[6] As such, HbF enhances the fetus' ability to extract oxygen from the placenta. HbF constitutes a small fraction of the total hemoglobin in adult red blood cells (0.3% to 1.2%), in which it is largely restricted to a small subset of circulating erythrocytes (0.2% to 7% of the total cells), termed *F cells*.[7,8] Production of HbF in normal adults is largely genetically controlled as demonstrated by studies in twins and familes.[9-13] During the first trimester in utero, embryonic hemoglobins with differing subunit composition are found in the yolk sac–derived macrocytic (or primitive) red blood cells.[1]

The genes that encode the globin polypeptides are organized into two small clusters.[2,4,5,14,15] The α-like genes are located near the telomere of the short arm of chromosome 16 (16p13.3), whereas the β-like genes reside on chromosome 11 at band 11p15.5.[16,17] A schematic diagram of the human globin genes and the composition of the various hemoglobins are shown in Figure 21-2.

Figure 21-2 Chromosomal organization of the globin genes and their expression during development. The *blue boxes* indicate functional globin genes, whereas the *yellow boxes* indicate pseudogenes (see text). The Θ1 globin gene is depicted by a *brown box* and is expressed at very low levels compared with the adult α-globin genes. The scale of the depicted chromosomal segments is in kilobases of deoxyribonucleic acid. The switch from embryonic to fetal hemoglobin occurs between 6 and 10 weeks of gestation, and the switch from fetal to adult hemoglobin occurs at about the time of birth. *Hb,* Hemoglobin.

The α-globin gene cluster contains three functional genes, ζ, α_2, and α_1, oriented in a 5′-to-3′ direction along the chromosome.[2,15,18,19] ζ-Globin, encoded by the ζ gene, is found in two embryonic hemoglobins, Hb Gower-1 ($\zeta_2\varepsilon_2$) and Portland ($\zeta_2\gamma_2$).[20] The duplicated α-globin genes (α_1 and α_2) encode identical polypeptides. DNA sequence analysis has revealed three additional globin gene–like sequences in the cluster: pseudo-ζ (ζ_1), pseudo-α_1, and pseudo-α_2.[2,15] Although they resemble the functional genes, sequence differences in coding or critical regulatory regions render these genes inactive, and hence they are referred to as pseudogenes.

Five functional genes, ε, ${}^{G}\gamma$, ${}^{A}\gamma$, δ, and β, are present within the β-like cluster and arranged in a 5′-to-3′ direction as they are expressed during development.[21-24] The product of the embryonic ε gene is found in the embryonic hemoglobins Hb Gower-1 ($\zeta_2\varepsilon_2$) and Hb Gower-2 ($\alpha_2\varepsilon_2$). The fetal γ genes are duplicated but encode globins differing only at amino acid 136; ${}^{G}\gamma$-globin and ${}^{A}\gamma$-globin contain a glycine or alanine residue, respectively. ${}^{G}\gamma$- and ${}^{A}\gamma$-globins are both found normally in HbF ($\alpha_2\gamma_2$). The δ-globin gene encodes a polypeptide differing in only 10 of 146 residues from β, and yet it is expressed at a very low level in adult red blood cells (<3% of β). The poor expression of δ-globin is attributed to differences in critical regulatory sequences[25] within the gene that appear to inhibit messenger ribonucleic acid (mRNA) processing[26] and the inherent instability of δ mRNA.[27] Only a single functional β-globin gene is present in the cluster. β-Globin is the predominant β-like globin in adult red blood cells, in which HbA ($\alpha_2\beta_2$) accounts for more than 95% of the total hemoglobin.

The relative synthesis of individual globin chains, the major sites of erythropoiesis during development, and major regulators of this process (discussed later) are depicted in Figure 21-3.[1,4,28-30] Embryonic hemoglobins are expressed nearly exclusively in primitive nucleated red blood cells differentiating in the yolk sac blood islands. HbF production commences during the next wave of erythropoiesis in the fetal liver. Fetal liver–derived red blood cells lose their nuclei as terminal maturation occurs, whereas the primitive, yolk sac–derived cells remain nucleated. The transition from HbF to HbA coincides approximately with the switch from fetal liver to bone marrow erythropoiesis. Despite this correlation between the site of erythropoiesis and the hemoglobins expressed, careful analysis of tissues derived from experimental animals and human fetuses has shown that embryonic hemoglobins are synthesized in the liver as well as the yolk sac and that HbF is produced in the bone marrow as well as the liver. The developmental switches in hemoglobin expression are related to the time of gestation rather than the anatomic site of erythropoiesis per se.

Globin Gene Structure

The globin genes were among the first eukaryotic genes isolated by recombinant DNA cloning methods in the late 1970s. Subsequent work provided the entire DNA sequences of the human α- and β-globin gene clusters and extensive sequences of other vertebrate globin complexes. These data have been invaluable in determining the mutations underlying thalassemia syndromes and in manipulating gene regulatory regions.

Intervening Sequences or Introns

A remarkable finding was made on initial study of the globin genes: the coding region, rather than being organized in a single continuous unit, is interrupted by noncoding DNA known as intervening sequences (IVSs), or introns. Most eukaryotic genes contain one or more introns. As indicated in Figure 21-4, globin genes are interrupted at two positions. The discontinuous nature of the coding region of globin genes poses a formidable problem for the formation of mRNA that must be translated into globin polypeptides on cytoplasmic ribosomes. Transcription of a globin gene generates a precursor mRNA containing introns. Formation of mature mRNA is accomplished by posttranscriptional processing, termed *RNA splicing*. The pathway of RNA processing is depicted in Figure 21-5.

RNA splicing must be executed with exquisite precision for functional mRNA to be generated. Because translation of mRNA proceeds by the reading of triplets (codons), excision of introns needs to be accurate to the nucleotide; otherwise, shifts in the reading frame of the translated polypeptide will result. RNA processing is guided by specific sequences, known as splice site consensus sequences, located at the 5′ and 3′ boundaries of the introns. The donor site, which marks the 5′ end of the intron, generally conforms to the sequence 5′ (C/A) AG′*GT*(A/G)AGT, where the prime sign indicates the position of splicing and GT is an essentially invariant dinucleotide at the 5′ end of the intron. The acceptor site, which defines the 3′ end of the intron, usually fits the consensus 5′ $(T/C)_n$N(C/T)*AG*′G, where *n* is 11 or greater, N is any nucleotide, the prime sign indicates the site of splicing, and AG is an essentially invariant dinucleotide. Excision of introns generally occurs between the dinucleotides GT and AG, known as the GT-AG rule.

Conserved Features of Mature Globin mRNA

Sequences of human globin genes represented in processed globin mRNA include additional segments located before (5′) and after (3′) the coding region. These untranslated regions are depicted in Figure 21-5. In addition, the mature mRNA is modified at both termini. At the 5′ end, a methylated guanylic acid (m^7G) cap structure is present. A variable number of adenylic acid residues are added at the 3′ end and constitute a poly(A) tail. The 5′ cap structure appears to be important for efficient initiation of mRNA translation, whereas the poly(A) tail contributes to mRNA stability. Overlapping the beginning of the mRNA sequence in genomic DNA are sequences that aid in directing the initiation of transcription to the proper site. In some eukaryotic genes these sequences conform to an initiator (Inr) consensus element.[31] The human β-globin gene has been shown to possess an Inr element that is functional in transcription reactions performed in vitro.[32]

Polyadenylation at the 3′ end of mRNA precursors depends on a signal in the 3′-untranslated region, generally AAUAAA (AATAAA in genomic DNA). The

Figure 21-3 Erythroid cell differentiation, transcriptional regulators of the globin genes, the β-globin gene locus, sites of erythropoiesis, and the pattern of globin biosynthesis during development. The top panel shows the pattern of differentiation from multipotent progenitors to mature red blood cells. Regulators of β-like globin gene expression, including BCL11A, GATA1, KLF1/EKLF, and MYB, are shown with arrows depicting the site of action of these factors. Some regulators, such as BCL11A, act directly at the β-globin locus shown below the diagram. Other regulators, such as MYB, act through unclear mechanisms to affect globin gene regulation. This may be either an indirect affect upon erythropoiesis or a direct activity at the β-globin locus. Nucleated megaloblasts, which are produced predominantly in the yolk sac, are replaced by macrocytic fetal red blood cells produced in the liver and subsequently in the spleen and bone marrow. The height of the shaded area approximates the proportion of circulating red blood cells produced by each organ. Globin biosynthetic measurements were made to obtain the data shown in the lower part of the figure. *HS,* Hypersensitivity site; *LCR,* locus control region.

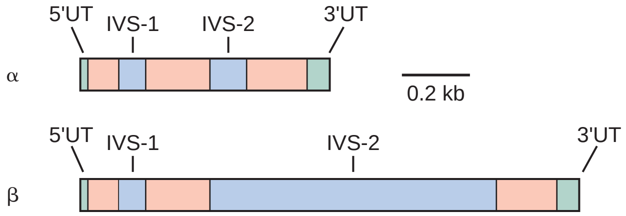

Figure 21-4 Structure of the human α- and β-globin genes. Untranslated (UT) regions, exon, and intervening sequences (IVS, introns) are depicted by *green*, *salmon*, and *blue boxes*, respectively.

mechanism of modification of the 3′ end is complex and involves not only polyadenylation but also cleavage of the precursor RNA because the primary RNA transcript extends several hundred nucleotides past what becomes the position at which the poly(A) tail is added.

Translation of mRNA into a polypeptide proceeds by the reading of triplets (codons) on cytoplasmic ribosomes. The first AUG codon (specifying methionine) present in the mRNA specifies the start site for translation of the mRNA into protein and is embedded in a sequence context (the Kozak consensus sequence, typically CC[A/G] CC*ATG*G) that signals the binding of translation initiation factors and ribosomes to the mRNA. Usually the amino-terminal methionine residue is removed from the growing polypeptide chain even before its synthesis is completed. Termination of polypeptide chain translation is directed by the termination codons UAA, UAG, or UGA. Mutation of these codons allows continued translation into the 3′-untranslated sequences of mRNA, as occurs in selected α-globin chain variants associated with α-thalassemia (discussed later).

As briefly reviewed earlier, the formation of functional mature mRNA demands extraordinary precision and depends on highly conserved sequence elements. As exemplified by the thalassemia syndromes, point (or other) mutations in these signals lead to reduced or absent polypeptide chain synthesis, which is the hallmark of thalassemia. Mutations causing thalassemia involve all phases of gene expression, including gene transcription, RNA splicing, integrity of the coding sequence, 3′ polyadenylation, and translation initiation (discussed later).

Regulation of Globin Gene Expression

Globin genes in all vertebrates are expressed in a tissue-specific and developmentally programmed manner. Their transcription is activated only within developing erythroid precursor cells. Moreover, individual globin genes are expressed at different developmental stages. Hence within the genes of the β cluster, globins are expressed at the embryonic (ε), fetal (γ), or adult (β and δ) stages, whereas within the α cluster, embryonic (ζ) and adult (α) chain expression is seen. A central problem posed by the organization of the globin gene clusters is how these patterns of tissue- and developmental-stage specificity are achieved. Recent findings from human genetic studies have begun to elucidate the molecular control of this developmental switch in the β-globin gene cluster and are discussed later in this chapter.

Proximal Regulatory Sequences and Transcription Factors

Several conserved sequence elements (motifs) in the 5′-flanking sequences of globin genes comprise the promoter, a region required for accurate and efficient transcription of genes by RNA polymerase II.[33-36] Promoters of vertebrate globin genes are similar in overall configuration and subset of motifs present but differ in their detailed organization and sequences. Promoters generally cooperate with more distant regulatory elements, termed *enhancers*, to stimulate transcription.[37-39] As discussed later, globin gene promoters appear to interact in a synergistic fashion with very powerful distant elements known as locus control regions (LCRs).

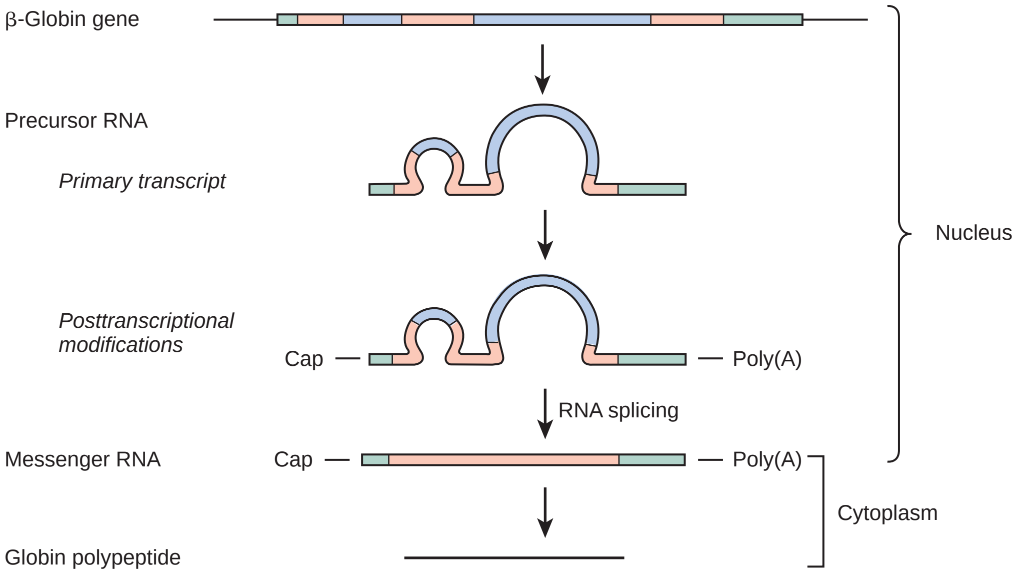

Figure 21-5 Expression of the β-globin gene. Transcription of the gene generates the precursor ribonucleic acid (RNA), which is processed by RNA splicing to form messenger RNA.

The TATA (or ATA) box is a motif seen in nearly all promoters, including those of the globin genes. The TATA box, typically located 20 to 30 base pairs (bp) upstream from the transcription start site, constitutes the binding site for a general transcription factor, the TATA-binding protein (TBP).[40-42] Binding of TBP to the TATA box is the first step in the assembly of a basal transcription complex (often termed *TFIID*) that includes many additional proteins (such as TFIIA, TFIIB, TFIIE/F, and TFIIH) and RNA polymerase II.[36] Mutations within the TATA box, as occur in some types of β-thalassemia,[43-49] decrease the binding of TBP to the promoter and decrease transcription.[40,41,50]

DNA sequence motifs located upstream of the TATA box bind proteins that interact with the general transcription machinery through protein-protein contacts with the TFIID complex and other associated proteins.[35,37,38,42] These promoter-bound proteins may either increase (activate) or decrease (repress) the rate of transcription. A small set of motifs are consistently present in globin gene promoters, including the CCAAT box, the CACC box, and GATA consensus sequences. Each motif may be viewed as a potential binding site for one or multiple transcription factors, which are either tissue restricted or ubiquitous in their cellular distribution.

Transcription factors are typically viewed as modular proteins made up of two domains that fulfill different functions: a DNA-binding domain responsible for sequence-specific DNA recognition and an activation (or repression) domain or domains that interact with components of the basal complex to modulate transcription. Additionally, some transcription factors may function to recruit activities that modify the histones around which DNA is wrapped to make chromatin. These modifications can indirectly alter the activity of the basal transcriptional complex. It is currently believed that transcriptional specificity is achieved by functional cooperation and interaction between cell-restricted and general transcription factors. As background for understanding globin gene control, the presently characterized erythroid-enriched transcription factors are reviewed here. For additional discussion of these proteins, readers are referred elsewhere.[51,52]

The consensus motif (A/T)GATA(A/G), known as the GATA motif, is found in the promoter region of most vertebrate globin genes and binds an abundant erythroid-restricted transcription factor, GATA1. GATA motifs have been identified in the regulatory elements of virtually all erythroid-expressed genes, consistent with the notion that GATA1 should serve a critical role in erythroid gene expression. As noted later, multiple GATA sites are also present within distant regulatory elements. The essential role of GATA1 in erythroid development was formally demonstrated through gene targeting experiments in mouse embryonic stem cells. Disruption of the single X-chromosome *GATA1* gene in totipotent embryonic stem cells prevents their development into normal erythroid cells. Naturally occurring but rare hypomorphic mutations of GATA1 in humans have been shown to cause β-thalassemia or disrupt normal erythroid development.[53-59] The GATA1 protein is a member of a small family of related "GATA factors" that are distinguished by a novel zinc-finger DNA-binding domain. In addition to merely specifying DNA recognition, this domain also mediates protein-protein interactions. Accordingly, GATA1 is able to interact physically with other GATA1 molecules or with other types of zinc-finger proteins, including the ubiquitous CACC- or GC-binding factor Sp1, the transcription factor erythroid Krüppel-like factor (EKLF), and a specific cofactor called FOG-1 (for "friend of GATA1"[60,61]; discussed later). It is envisioned that through its multiple physical interactions, GATA1 cooperates with other transcription factors, perhaps bound to DNA at distant sites, to program erythroid-specific transcription.

CACC motifs, which are represented by diverse sequences within globin and other gene promoters, bind a variety of transcription factors. Many CACC sequences are recognized by Sp1, a ubiquitous zinc-finger activator protein.[62] A particular CACC motif, CCACACCCT, is found in the adult β-globin gene promoter and is recognized with high affinity by the erythroid-specific protein EKLF (also known as KLF1). The functional relevance of this binding site has been established through naturally occurring mutations that lead to β-thalassemia (discussed later). In addition, gene targeting (or knockout) experiments in mice have formally established that EKLF/KLF1 is necessary for efficient β-globin transcription in vivo.[63]

A third erythroid transcription factor, known as NF-E2, binds to an extended motif—(T/C)TGCTGA(C/G)TCA(T/C)—that is found within some distant regulatory elements (discussed later) and a small subset of erythroid promoters but not within globin gene promoters. NF-E2 is a heterodimer of two polypeptides of the basic domain–leucine zipper (or "b-zip") class of transcription factors.[64,65] One subunit of NF-E2 is tissue restricted, whereas the other is ubiquitous. Although NF-E2 is essential for globin gene expression in mouse erythroleukemia cells in tissue culture,[66,67] its role in vivo appears to overlap that of one or more unknown factors that may act through the same target sites in DNA.[68]

Locus Control Regions and Chromatin Domains

How is globin gene transcription activated and developmentally controlled? Inspection of the DNA sequences of globin gene promoters in the early 1980s failed to provide substantive insight. Initial attempts to dissect control elements involved introducing globin genes into the germline of mice by oocyte injection but were plagued by low-level and erratic transgene expression. Nonetheless, it was possible to show that low-level stage specificity was imparted by the human β- and γ-globin gene promoters. For example, when the human β-globin promoter is introduced into transgenic mice, it directs gene expression only in adult erythroid cells,[69-72] whereas the human γ-globin promoter is active only in embryonic erythroid cells (mice do not have an HbF stage).[73,74]

These early globin gene regulation studies suggested that critical regulatory elements required for high-level expression were missing from the immediate vicinity of the genes themselves. When sensitivity to digestion by the enzyme DNase I was used as an indicator of chromatin structure in the mid 1980s, regions of extreme sensitivity (hypersensitivity sites [HSs]) were identified far upstream (≈30 to 50 kilobases [kb]) of the adult human β-globin gene.[75,76] Four subregions were delimited; they are present in the chromatin of erythroid, but not in nonerythroid cells. An additional site located even further upstream was found in all tissues. In a formal test of their functional relevance, the HSs were linked to a human β-globin and introduced into the germline of mice. Remarkably, transgenic mice then expressed the human β-globin gene at a level equivalent to that of the endogenous mouse β gene.[77] Further studies showed that the transgene is expressed not only in a tissue-specific manner but also in a copy number–dependent fashion, independent of the chromosomal site of integration. These HSs comprise an essential distal regulatory domain, now referred to as the LCR (see elsewhere[51,52] for a more detailed history and discussion).

Other globin gene clusters also contain erythroid-specific DNase I HSs. A segment of extreme DNase I hypersensitivity (known as HS-40) located far upstream of the human α-globin genes serves as an enhancer for the α locus. HS-40, however, does not display the full properties of an LCR because it does not direct copy number–dependent transgene expression.[78] Nonetheless, the in vivo relevance of both the β-LCR and HS-40 is underscored by the discovery of patients with thalassemia who have specific deletions in these regions (discussed later).

The human β-LCR, HS-40, and analogous regions studied in other species are composed of cores, each encompassing a DNase I HS. Cores are approximately 200 to 300 bp in length. Remarkably, within the cores three major protein-binding sites are consistently found: GATA, AP-1 (NF-E2), and CACC sequences. The position-independent activity of the β-LCR correlates best with the presence of GATA and CACC motifs, particularly within the subregion known as HS-3. Enhancer activity of the LCR, particularly within subregion HS-2, requires the NF-E2 motif. The protein-binding motifs within the LCR are also found in globin and other erythroid-expressed gene promoters. To date, no protein-binding sites unique to LCR elements have been identified. Hence the distinctive properties of the LCR (or HS-40) appear to reflect the synergistic interactions of more typical transcription factors rather than the action of a new set of regulatory proteins.

The discovery of distant control elements, marked by DNase I hypersensitivity, emphasizes the relationship between chromatin structure and globin gene regulation, an association solidified by the unraveling of a rare syndrome, α-thalassemia with X-linked mental retardation.[79] This condition results from mutations in a gene designated *XH2* (or *ATRX*) that encodes a member of the helicase superfamily.[80] Such proteins, which are often involved in DNA recombination and repair and in the regulation of transcription in *Drosophila*, yeast, and mammals, appear to influence transcription in a global manner by altering chromatin structure.

Regulation at a Distance: Globin Gene Switching

How do LCR sequences influence globin gene transcription over large distances (>50 kb), and how are the individual globin genes developmentally regulated? Two formal possibilities have been considered. On one hand, the LCR might merely provide an environment conducive for activation of the downstream globin genes. The globin genes would be autonomously regulated; that is, the developmental profile of their expression would be intrinsic to the individual genes (and presumably determined by their promoters). The "influence" of the LCR is most simply viewed as reflecting physical association of the LCR with globin genes brought into apposition by chromosomal looping. On the other hand, sequential activation of the particular genes might depend (at least in part) on competition of each gene for influence of the LCR such that only one gene-LCR interaction would be productive on a single chromosome at any time. The outcome of the competition would be dependent on the array of proteins bound not only at each promoter but also at specific sites in the LCR. Data in favor of both autonomous and competitive mechanisms of regulation have been obtained (see Orkin[51] for a detailed discussion).

The human embryonic ζ- and ε-globin genes appear to be largely autonomously regulated. Transgenes that contain LCR are expressed during embryonic erythropoiesis (the yolk sac stage) and then extinguished during the fetal liver stage. The information required for shutoff is contained near the globin genes, and competition by adjacent globin genes is not required. Shutoff is hypothesized to reflect the action of repressors, or silencer proteins, that bind the gene promoters. Motifs within the human ε-globin promoter are involved in silencing bind GATA1 and a ubiquitous factor, YY1.[81]

The competitive model of gene regulation is based on experiments in chicken red blood cells that demonstrate competition between the chicken β- and ε-globin gene promoters for a single enhancer located between the genes.[82] In the chicken it has been proposed that an adult stage–specific factor (NF-E4) favors interaction of the β promoter with the enhancer to the exclusion of the ε promoter. In an analogous fashion, data suggest that the human β-globin gene may be negatively regulated in a competitive fashion by the γ-globin gene. Whereas the γ gene is largely autonomously regulated, the β-globin gene is silenced in the embryonic and early fetal stage by a linked γ gene (a γ gene in *cis* to β). Shutoff of the γ gene, presumably as a result of repressors (or silencers), allows the adult β-globin to be expressed. Although other models are theoretically possible, the capacity of the LCR to act at a distance in regulating activation of globin genes is most compatible with the formation of physical contacts between the LCR (or subregions thereof) and their associated proteins with regulatory elements neighboring the genes themselves. Stage-specific and competitive regulation would therefore reflect engagement of the LCR with genes one at a time. LCR-gene interactions probably have intrinsic stabilities and off-rates such that a single erythroid cell might express more than one globin over time, even from a single chromosome. Experiments examining nascent human globin RNA along the β-gene complex tend to support such models and lend credence to the notion that chromosomal looping brings the LCR and individual genes in apposition. Evidence for LCR interactions with the proximal promoter regions of both the β- and α-globin genes has recently been directly demonstrated by using novel in vivo biochemical approaches.[83-85] Dynamic interactions between the β-LCR and the γ- and β-globin genes appear to underlie the reciprocal expression of these genes in erythroid cells and provide hope that subtle alterations in the nuclear environment may facilitate reactivation of γ-globin genes in patients with hemoglobinopathies such as sickle cell anemia or β-thalassemia. Recent work suggests that looping of the LCR itself in close proximity to the globin genes may be sufficient to allow for at least partial activation of transcription of these genes, as least in mouse models.[86] This group has recently gone on to demonstrate that such modulation of looping is sufficient for activation of embryonic or fetal hemoglobin genes in mouse models and human cells. This offers the prospect that such approaches could be therapeutically useful.[86a]

Recent Insights into Developmental Globin Gene Switching from Human Genetics

The molecular basis of the fetal-to-adult hemoglobin switch had remained an enigma over the course of nearly three decades. Although regulators of globin gene regulation, including GATA1, EKLF/KLF1, and NF-E2, had been identified, none of these regulators appeared to be sufficient to confer the stage-specific expression properties that are observed for the γ- and β-globin genes. By following up on the results of genome-wide association studies (GWAS)—a technique by which associations between common polymorphisms across the genome and various traits are tested—the first developmental stage-specific regulator of the fetal-to-adult hemoglobin switch, BCL11A, was identified (see Fig. 21-3).[87] Initial GWAS had identified a robust signal of association on chromosome 2 with HbF levels in both healthy persons and in patients with sickle cell disease.[88-90] This signal was most robust within a regulatory element of the gene *BCL11A*, which encodes a multizinc finger transcriptional regulator that had previously been implicated in B lymphocyte and neural development. By examining the hypothesis that BCL11A may also regulate HbF expression, it was found that reducing BCL11A expression allowed robust reactivation of HbF in adult cells.[91] Consistent with this finding, BCL11A is developmentally regulated and its expression is maximal in erythroid cells with little or no γ-globin expression. Moreover, BCL11A occupies regulatory elements within the β-globin locus, although it does not bind the promoter of the γ-globin genes. BCL11A holds tremendous promise as a therapeutic target for HbF induction in patients with β-thalassemia or sickle cell disease. Indeed, a proof of concept study has shown that removal of BCL11A in the hematopoietic system of mouse models of sickle cell disease can result in amelioration of disease in this model system.[92] An erythroid-specific enhancer element of BCL11A has recently been identified and holds promise for tissue-specific targeting of BCL11A expression.[92a] Furthermore, recent insight from rare human deletions within the β-globin gene cluster, which will be discussed in more detail later in this chapter, are providing important mechanistic insight into how BCL11A acts to regulate the fetal-to-adult hemoglobin switch.[93] It is likely that further studies of the type described here will lead to targeted approaches by which BCL11A activity can be selectively modulated.

In addition to the insight gained into hemoglobin switching from studies of BCL11A, other work has suggested that rare mutations in KLF1/EKLF may lead to elevations of HbF levels in patients and that this transcription factor may be involved in hemoglobin switching through the regulation of BCL11A (see Fig. 21-3).[94,95] However, other mutations in KLF1 result in either a significant congenital anemia or have little affect upon globin gene regulation, suggesting that other factors may modify the observed phenotypes in the patients.[87,96-98] Therefore further study of KLF1 and its role in this regulatory process is needed. In addition to the GWAS highlighting the role of BCL11A in HbF regulation, these studies have also suggested a role for the *MYB* gene in silencing of HbF.[88,89,99,100] This role has been substantiated through functional studies that have shown that reducing MYB levels can robustly activate γ-globin expression.[101,102] GWAS of β-thalassemia patient populations have shown that variants upstream of *MYB* can have a profound affect on the clinical course, and therefore MYB may be an important therapeutic target.[103,104] However, further studies are needed to better understand the exact mechanism by which MYB regulates globin gene expression (see Fig. 21-3).

CLASSIFICATION OF THE THALASSEMIAS

The hallmark of thalassemia syndromes is decreased (or absent) synthesis of one or more globin chains. The designation α- and β-thalassemia refers to deficits in α- and β-globin production, respectively. The α- and β-thalassemias include clinical syndromes of varying severity (Table 21-1). Knowledge of molecular genetics provides a framework in which to consider their clinical heterogeneity.

Because the structural gene for α-globin is duplicated on chromosome 16, each diploid cell contains four copies of the α-globin gene. The four α-thalassemia syndromes—silent carrier, α-thalassemia trait, hemoglobin H (HbH)

TABLE 21-1 Clinical Classification of the Thalassemias

Clinical Classification	Description
Silent carrier (α or β)	Hematologically normal
Thalassemia trait (α or β)	Mild anemia with microcytosis and hypochromia
HbH disease (α-thal)	Moderately severe hemolytic anemia, icterus, and splenomegaly
Hydrops fetalis (α-thal)	Death in utero caused by severe anemia
Severe β-thalassemia (Cooley anemia)	Severe anemia, growth retardation, hepatosplenomegaly, bone marrow expansion, and bone deformities
Thalassemia major	Transfusion dependent
Thalassemia intermedia	No regular transfusion requirement

HbH, Hemoglobin H; *thal,* thalassemia.

disease, and hydrops fetalis (see Table 21-1)—reflect the inheritance of molecular defects affecting the output of one, two, three, or four of the α-globin genes, respectively. More than 30 different mutations affecting one or both α-globin genes on a chromosome have been described. Some mutations abolish expression of an α-globin gene (α^0), whereas others reduce expression of the gene to a variable degree (α^+). Marked genetic and clinical heterogeneity occurs within the four general categories of α-thalassemia. Heterogeneity arises because the syndrome in any given person may represent a combination (or so-called interaction) of 2 of the 30 or more mutations that have been described.

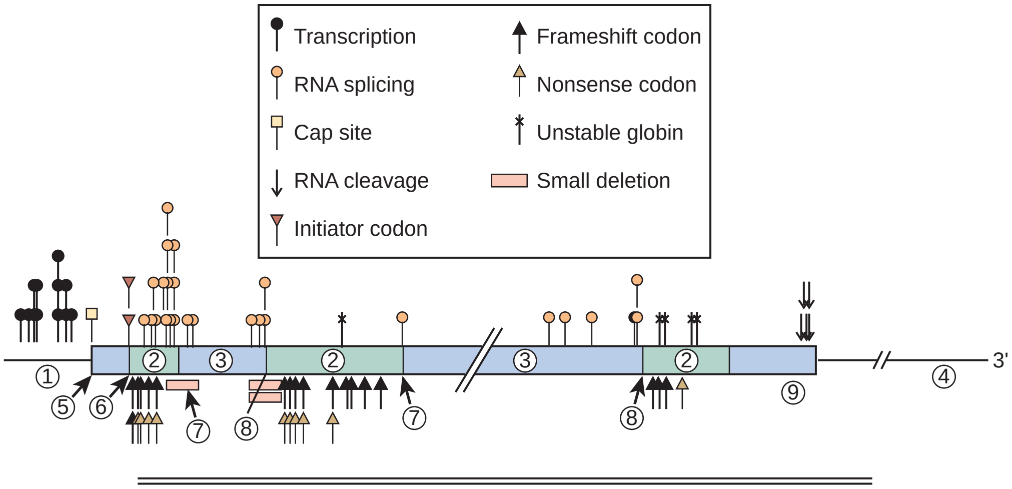
The β-thalassemias also include four clinical syndromes of increasing severity—silent carrier, thalassemia trait, thalassemia intermedia, and thalassemia major (see Table 21-1).[1,3,105,106] In contrast to the α-thalassemias, the four classes of β-thalassemia are not correlated with the number of functioning genes. Because a single functional β-globin gene resides on each chromosome 11, a diploid cell normally has two β-globin genes. The clinical heterogeneity of the β-thalassemias represents the diversity of specific mutations that variably affect β-globin gene expression. Almost exclusively, these mutations involve the β-globin gene rather than an unlinked genetic determinant. Many mutations eliminate β-gene expression (β^0), whereas others cause a variable decrease in the level of β-gene expression (β^+).[3,106] The capacity of individual patients to synthesize γ-globin modulates the clinical severity. Such is the case because the severity of thalassemias is determined by the degree of globin chain imbalance rather than by the absolute level of either α- or ββ-globin synthesis per se.[107-109,110,111] Substantial synthesis of γ-globin in the marrow cells of persons with β-thalassemia lessens the extent of chain imbalance and therefore improves red blood cell production.[112-114] Particular mutations of the β-globin gene in β-thalassemia appear to affect γ-globin gene expression directly. However, some persons with otherwise severe β-thalassemia may co-inherit additional genetic determinants that enhance the synthesis of HbF. Indeed, in patients with β-thalassemia who do not receive transfusions, HbF levels are strongly associated with clinical severity.[115] Coincident inheritance of an α-thalassemia mutation also reduces chain imbalance in patients with homozygous or heterozygous β-thalassemia.[116] Clinical severity in any individual patient represents the outcome of these complex genetic interactions.

Origin of Thalassemia Mutations: The Influence of Malaria

Mutations causing thalassemia have arisen spontaneously. The nearly exclusive distribution of lethal red blood cell disorders such as thalassemia, sickle cell disease, and glucose 6-phosphate deficiency in tropical and subtropical regions led Haldane in 1949 to propose that the heterozygous carrier state for these conditions confers a selective advantage in locations where malaria is endemic.[117] The incidence of these genes in a population is determined by the balance between premature death of homozygotes and increased fitness of heterozygotes. The frequency of β-thalassemia mutations is high (>1%) in regions such as the Mediterranean basin, northern Africa, Southeast Asia, India, and Indonesia but uncommon in northern Europe, Korea, Japan, and northern China.[3,118,119] The incidence of β-thalassemia trait may exceed 20% in some villages in Greece.[120] α-Thalassemia is perhaps the most common single gene disorder in the world.[2] The frequency of α^+-thalassemia alleles ranges from 5% to 10% in the Mediterranean basin,[121] 20% to 30% in portions of West Africa,[122] and 68% in the southwest Pacific.[123] The incidence of α-thalassemia is less than 1% in Britain, Iceland, and Japan.[124,125] Although the incidence of malaria and the rate of occurrence of thalassemia are not always inversely correlated, the anomalies and inconsistencies seem to be the result of genetic drift, migration, and demographic changes that have occurred in the last 10,000 years.[126]

Additional epidemiologic studies have provided further evidence for the validity of the "malaria hypothesis" in both α- and β-thalassemia.[123,127-134] Siniscalco and colleagues[127] showed that β-thalassemia is uncommon in inhabitants of the mountainous areas of Sardinia, where malaria is rare, compared with the incidence in coastal populations. In Melanesia, α-thalassemia is correlated with malaria across both latitude and altitude.[123] β-Thalassemia in Melanesia is also associated with malarious coastal regions.[131] Williams and colleagues[135] found that children with α-thalassemia trait appear to have a higher incidence of malaria in childhood that appears to confer subsequent immunity to more severe malarial infections. Follow-up studies in other populations have demonstrated that although α-thalassemia does not confer a reduced risk of malarial infection, it does dramatically reduce the incidence of severe malarial complications.[136,137]

The cellular mechanisms responsible for the selective advantage of thalassemia heterozygotes remain incompletely defined. Cultured erythrocytes containing high concentrations of HbF retard the growth and development of *Plasmodium falciparum*.[138] β-Thalassemia heterozygotes have a delayed disappearance of HbF in the first year of life,[1] which might provide protection from potentially fatal cerebral malaria early in life as the passive immunity acquired in utero wanes. Until recently, however, investigators were unable to document decreased invasion or growth of *P. falciparum* in red blood cells from thalassemia heterozygotes except under conditions of unusual oxidant stress.[99,139] Using modified tissue culture conditions, Brockelman and colleagues[140] and, more recently, Pattanapanyasat and colleagues[141] demonstrated decreased parasite multiplication in the red blood cells of β-thalassemia heterozygotes. They theorized that *P. falciparum* resistance was a consequence of the inability of the parasite to acquire sufficient nutrients from the digestion of hemoglobin in thalassemic red blood cells. In one study, red blood cells with α- and β-thalassemia trait bound greater levels of antibody than did control cells, which could lead to greater removal of parasitized red blood cells and hence provide protection.[142] Recent studies have suggested that parasitized red blood cells from α-thalassemia heterozygotes may have altered



1. PROMOTER: DNA sequences required for accurate and efficient initiation of transcription.
2. EXONS: DNA that specifies the amino acid sequence of the polypeptide.
3. INTRONS: DNA that interrupts the coding sequence of the gene.
4. ENHANCER: DNA sequences that increase promoter activity at a distance and independent of orientation relative to coding sequence.
5. CAP SITE: Position where transcription of gene into RNA begins.
6. TRANSLATION INITIATION SITE: Position where translation of mRNA into protein begins.
7. SPLICE DONOR SITE } Sequences required for precise and efficient
8. SPLICE ACCEPTOR SITE } removal of RNA transcribed from introns.
9. RNA CLEAVAGE/POLYADENYLATION SIGNAL: Sequence that specifies the 3' end of the RNA transcript and the addition of the poly(A) tail.

membrane properties that more readily allow binding of antibody to the red blood cell and may promote more effective antimalarial immune responses.[143] Erythrocytes from persons with HbH disease also appear to inhibit *P. falciparum* in vitro.[140,144] Recently it has been suggested that rosette formation, the binding of uninfected red blood cells to *P. falciparum*–infected red blood cells, is decreased in persons with thalassemia because of reduced red blood cell size and that such impaired rosette formation may hinder the development of cerebral malaria by lessening sequestration.[145]

The difficulty of documenting the cellular mechanism of *P. falciparum* resistance in thalassemic erythrocytes in vitro suggests that the heterozygote advantage may be small. The high mortality associated with malaria in endemic regions is a powerful selective force that may be sufficient to amplify a small increase in fitness.

Classes of Mutations That Cause Thalassemia

Thalassemia is the consequence of mutations that diminish (or abolish) production of either the α or β chain of hemoglobin. Molecular cloning, DNA sequencing, and functional analysis of cloned genes have provided the tools with which to dissect the thalassemia syndromes. This analysis has revealed remarkable heterogeneity in the specific alterations in DNA that lead to these clinical syndromes.

Typically, single nucleotide mutations associated with thalassemia interfere with one of the critical steps in mRNA production (Fig. 21-6 and Table 21-2). Base substitutions alter promoter function, RNA processing, or mRNA translation or modify a codon into a "nonsense codon" that leads to premature termination of translation or substitution of an incorrect amino acid. Insertion or deletion mutations within the coding region of the mRNA create "frameshifts" that prevent the synthesis of a complete, normal globin polypeptide. Large deletions within the α- or β-globin clusters may remove one or more genes and alter regulation of the remaining genes in the cluster. The phenotype that results from the diverse mutations found in thalassemia is determined by the degree of inactivation of the affected gene or genes and the extent of associated increases in expression of other genes within the cluster. In the following section we discuss examples of such mutations. The discussion of various mutations is meant to illustrate different molecular mechanisms that

Hb, Hemoglobin; *IVS,* intervening sequence; *RNA,* ribonucleic acid.

*The position specifies the location in the gene at which the point mutation occurs. Positions are specified with reference to the start site for transcription (Cap site), the position within the intron (IVS), or the position of the codon.

†When more than one ethnic group is indicated, the mutation has had more than one origin.

‡Loss (–) or gain (+) of a restriction enzyme site with mutation is indicated; the remainder of the mutations can be detected with allele-specific oligonucleotides (see the section on direct detection of thalassemia mutations).

can lead to thalassemia and in no way is meant to be comprehensive. A comprehensive and regularly updated listing of all described mutations can be found at http://globin.cse.psu.edu/.

Mutations Affecting Gene Transcription

Point mutations within promoter sequences recognized by transcription factors tend to reduce the affinity with which these proteins bind and typically leads to reduced gene transcription. Analysis of the promoter for the β-globin gene in patients with β-thalassemia has identified a variety of mutations clustered in the ATA and CACC motifs (Fig. 21-7; see also Table 21-2).[3,40-46,146-149] These mutations are associated with preservation of some β-globin expression and hence are customarily associated with the phenotype of thalassemia intermedia. The C→T substitution at position –101, which results in a particularly mild defect, is associated with the "silent carrier" phenotype in heterozygous carriers.[146,150] Although the CCAAT box is highly conserved in globin genes, no mutations within this motif have been identified in thalassemia. Rare mutations in transcription factors that result in thalassemia have been detected, and exceedingly rare families have been identified in which a thalassemia mutation is unlinked to the globin clusters (see the section on mutations not linked to the globin gene clusters that alter globin gene expression).

Mutations of the ATA box presumably reduce binding of TBP and therefore lead to decreased transcription initiation. Substitutions in the CACC motifs decrease the affinity of binding by several transcription factors, including the erythroid-specific factor EKLF/KLF1 and the ubiquitous protein Sp1. Studies showing that mice engineered to lack EKLF experience lethal β-thalassemia at the fetal liver stage have established EKLF as a β-globin activator protein in vivo, and patients with mutations in EKLF have reduced production of the adult β-globin gene.[63,87,151] Human β-thalassemias resulting from

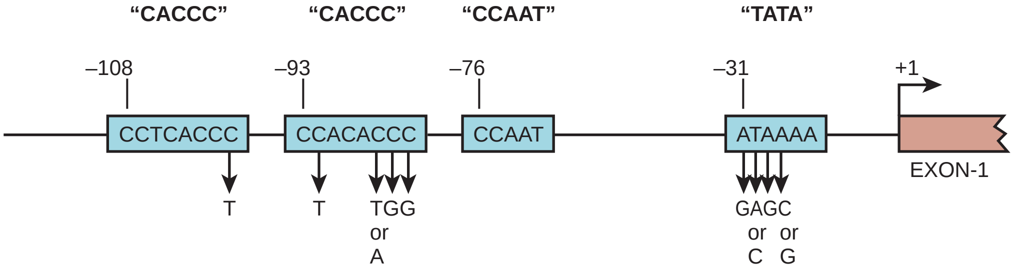

Figure 21-7 Point mutations in the β-globin gene promoter. The sequences of conserved motifs within the promoter and their distance from the transcription start site are indicated. A single base substitution at the indicated positions results in β⁺-thalassemia.

mutation of a single CACC motif are presumably mild because of the presence of one normal CACC motif within the promoter.

In addition to the protein-binding sites in the promoter, proper transcription depends on sequences surrounding the start site of transcription (known as +1). These sequences often display functional activity in in vitro assays and herald the binding of specific protein complexes to this type of element, termed the *Inr*. Mild β-thalassemia has been associated with a base substitution (A→C) at +1. This substitution has been shown to impair the β-globin Inr.[32] The proteins that mediate this effect are unknown.

A novel mechanism by which transcription at the α-globin locus can be disrupted has been described and serves as a paradigm for a unique class of mutations that can cause human disease. Higgs and colleagues[152] found a variant single nucleotide change upstream of the α-globin genes that creates a binding site for the transcription factor GATA1,[152] which in turn produces a novel promoter that competes with the endogenous α-globin promoters for interaction with upstream enhancer elements such as HS-40. As a result of this mutation, α-globin gene synthesis is reduced and α-thalassemia results. This mutation is present in approximately 4% of the Melanesian population.

RNA Processing Defects in Thalassemia

The importance of RNA splicing for the formation of functional mRNA cannot be overemphasized. As discussed earlier, removal of introns must be precise to the nucleotide for a continuous, translatable mRNA to be generated from an mRNA precursor. As soon as introns were discovered, it was hypothesized that mutations affecting RNA splicing would probably be involved in the thalassemia syndromes. Apart from its role in constructing a functional mRNA, RNA splicing also appears to be a determinant of mRNA stability[153,154] and is possibly coupled to RNA transport from the nucleus to the cytoplasm.[155]

Mutations That Alter Splice Junctions or Splice Consensus Sequences

Mutations at the 5′ donor site (GT)[149,156-163] or at the 3′ splice acceptor site (AG)[3,46,160,161,164-166] abolish proper splicing of the pre-mRNA transcript and result in α^0- or β^0-thalassemia (Fig. 21-8; see also Table 21-2). Substitutions at other sites within the splice junction consensus sequence have varied effects; because some correctly spliced RNA is produced, albeit a reduced amount, a β⁺-thalassemia phenotype ensues.[130,148,149,158,159,167-175]

Mutations within the splice site or the splice site consensus sequences favor improper processing of the mRNA precursor. These secondary splicing events, which are not seen under normal circumstances, occur at positions that resemble splice site consensus sequences. Splicing at these "cryptic" sites generates aberrantly processed, nonfunctional globin mRNA (see Fig. 21-8). Mutations within the β-globin IVS-1 splice donor site activate two cryptic donor sites in exon 1 and a third site in IVS-1,[149,161,176] whereas mutation in the IVS-2 splice donor activates a cryptic donor site in IVS-2.[162] Mutation of the IVS-2 splice acceptor site activates an upstream cryptic splice acceptor at position 579 in IVS-2.[46] These incorrectly spliced mRNA molecules sustain either insertions or deletions in the coding region and also shifts in the translational reading frame downstream of the cryptic splice site. The polypeptide synthesized beyond this point bears no resemblance to the globin chain and is often prematurely shortened by a termination codon encountered in the new reading frame.

Mutations within Exons That Create an Alternative Splice Site

RNA from β-thalassemia genes with mutations in the IVS-1 donor splice site may be processed via a cryptic splice donor site GTGG*T*GAGG in exon 1 (codons 24 through 27). Four independent mutations have been identified that activate this cryptic site in the presence of a normal IVS-1 splice donor site (Fig. 21-9; see also Table 21-2).[106,177,178,179] These mutations appear to enhance the ability of the cryptic site to compete with the normal site for binding of the splicing complex. A T→A mutation at codon 24 is "silent" at the translational level, yet approximately 80% of RNA transcripts are spliced at this incorrect site; hence, mild β⁺-thalassemia ensues. Two mutations—GAG→AAG in codon 26 and GCC→TCC in codon 27—lead to amino acid replacements that produce the hemoglobin variants HbE and Hb Knossos, respectively, in normally processed mRNA. Because a proportion of transcripts are aberrantly spliced, mild β⁺-thalassemia results. An analogous mutation in codon 19 produces β⁺-thalassemia with the hemoglobin variant Hb Malay,[180] representing mutations that lead to thalassemic hemoglobinopathies.

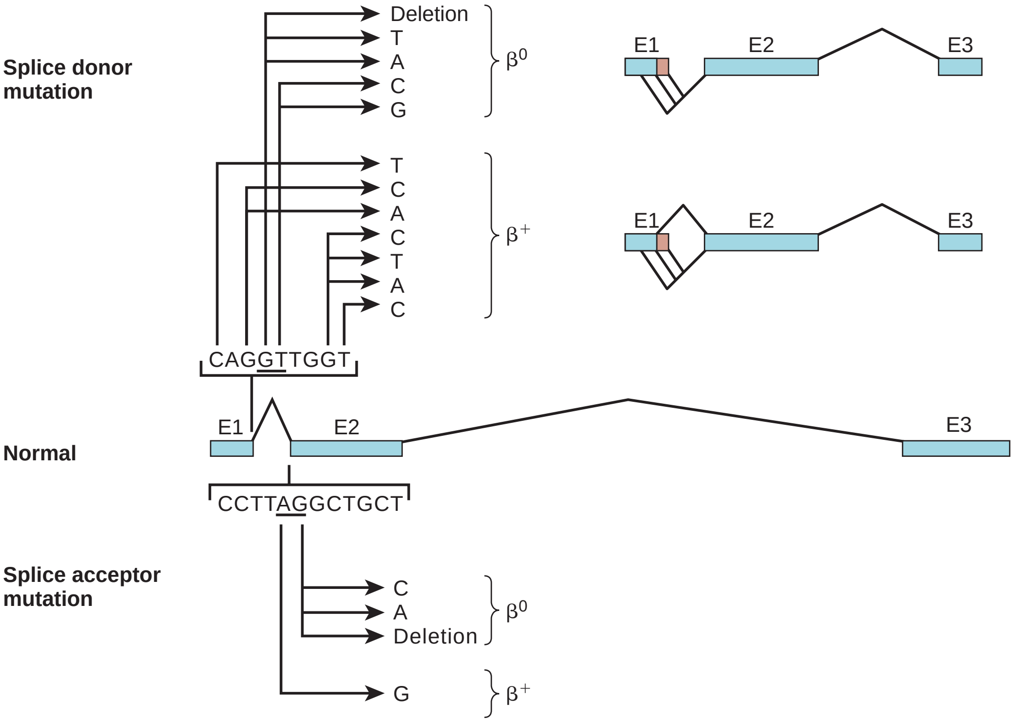

Figure 21-8 Examples of abnormal splicing that result from alterations in the splicing consensus sequences. The three β-globin gene exons are symbolized by *blue boxes*, the normal splicing pattern is illustrated by lines that project above the exons, and the splice donor and splice acceptor sequences of the first intron are shown. Mutations in the invariant GT dinucleotide of the splice donor site abolish normal splicing of the first intron and result in β^0-thalassemia, whereas mutations elsewhere in the consensus sequence preserve some normal splicing and cause β^+-thalassemia. Changes in the splice donor site are associated with abnormal splicing from three cryptic splice donors (lines that project below the exons); one site is within the first intron and results in the addition of intron sequences to exon 1 *(brown boxes)*. Similarly, changes in the invariant AG dinucleotide of the splice acceptor sequence are associated with β^0-thalassemia, whereas a mutation in an adjacent nucleotide causes β^+-thalassemia.

Mutations within Introns That Create an Alternate Splice Site

Mutations within β-globin IVS-1 may create a new splice acceptor sequence (Fig. 21-10; see also Table 21-2).[181-183] In the first of this class of mutations to be characterized, a G→A substitution at position 110 (19 nucleotides upstream of the normal intron/exon boundary), the majority of globin mRNA precursors are spliced at this alternate site.[181,182,184,185] Because the incorrectly spliced mRNA contains 19 nucleotides from IVS-1, a shift in the reading frame leads to premature termination of translation. A T→G mutation at position 116 of IVS-1 creates a new acceptor site that is used exclusively, thereby leading to little or no normal β-globin mRNA production and to β^0-thalassemia.[183]

Three mutations in IVS-2 create new donor sites and activate an upstream cryptic donor site located 579 nucleotides from the exon 2–IVS-2 boundary (see Table 21-2 and Fig. 21-10).[149,169,186] The consequence of these mutations is the insertion of a fourth "exon" derived from sequences within IVS-2. Although the normal donor and acceptor sites are unaffected, little or no correctly spliced β-globin mRNA may be produced.[149,169,186]

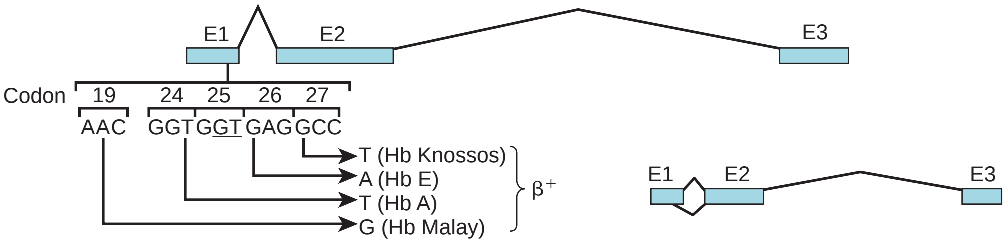

Figure 21-9 Mutations that create an alternate splice donor site in the first exon decrease but do not abolish the occurrence of normal splicing (pattern that projects above the exons) and are associated with splicing from the new site in the first exon (pattern that projects below the exons). Three of these mutations lead to the incorporation of a different amino acid into the β-globin chain derived from the decreased quantity of correctly spliced β-globin messenger ribonucleic acid and generate variant hemoglobins.

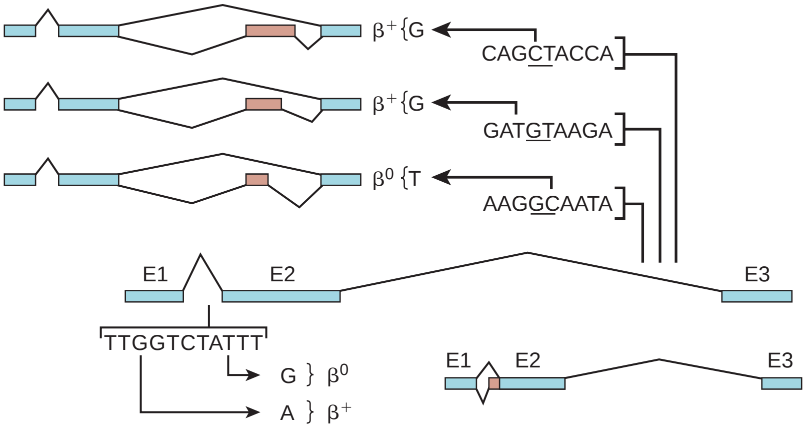

Figure 21-10 Mutations within introns that create a new splice site. Three mutations in the second intron create a new splice acceptor site (the invariant GT is underlined) and activate the identical cryptic splice donor site located just upstream. Abnormal splicing from these sites (pattern that projects below the exons) leads to the creation of a fourth exon *(brown boxes)* derived from sequences within the second intron. Two mutations in the first intron create a new splice acceptor site with the conserved AG dinucleotide, and abnormal splicing from this site (pattern that projects below the exons) adds sequences from the first intron to the beginning of the second exon.

RNA Cleavage and Polyadenylation Defects

Proper cleavage at the 3′ end of the pre-mRNA and subsequent poly(A) addition depend on the integrity of the AAUAAA signal in the 3′-untranslated region. The importance of the polyadenylation signal for efficient production of globin mRNA was first demonstrated in α-thalassemia.[187-189] An AAUAAA→AAUAAG mutation in the α_2 gene reduces the efficiency of cleavage-polyadenylation of precursor RNA and leads to "run-on" transcripts that terminate downstream of the gene (see Fig. 21-12). Mutations in the AAUAAA element have also been described in β-thalassemia,[148,190,191] in which the presence of elongated in vivo transcripts has been demonstrated.[190] The transcripts appear to terminate at the next AAUAAA signal, which is present approximately 900 nucleotides downstream of the normal cleavage site. These mutations lead to a moderate reduction in the level of β-globin mRNA and a β^+ phenotype.

Mutations Affecting mRNA Translation Initiation

Translation begins at an AUG codon that usually lies within the consensus sequence (GCC)GCC(A/G)CC*AT*GG.[192] Substitutions within the AUG codon abolish translation, whereas those in other positions of the consensus often result in less efficient initiation of translation.

Four mutations in α-globin genes alter the consensus sequence and impair translation (see Table 21-2). Three of them affect the AUG Inr.[193-195] No globin polypeptide is produced because the next downstream Inr is in a different reading frame. The fourth α-globin mutation in this class, found on a chromosome in which one α-globin gene was deleted, alters the consensus sequence by the deletion of two bp and reduces mRNA translation to 50% of normal.[196,197] Two AUG Inr mutations of the β-globin gene have been described, and both are of the β^0 type (see Table 21-2).[3,191]

Premature Termination (Nonsense) Mutations

Nucleotide substitutions within the coding region are innocuous if they occur in the third position of a codon and do not alter the amino acid inserted during translation. Substitutions that alter codons from one amino acid to another lead to hemoglobin structural variants. Some substitutions change a triplet coding for an amino acid to a stop codon (UAG, UUA, or UGA). Such chain termination (or nonsense) mutations abort mRNA translation and lead to the synthesis of a truncated polypeptide. Moreover, nonsense mutations also reduce the amount of stable mRNA generated, which is a reflection of coupling between mRNA biogenesis and mRNA translation (Fig. 21-11).[198]

Chang and Kan[199] described the first nonsense mutation in β-thalassemia in which a lysine codon at amino acid position 17 was converted to a stop codon (AAG→UAG). Although no β-globin chains were produced in vivo, complete translation of the abnormal mRNA could be achieved in a cell-free extract capable of protein synthesis by the addition of a "suppressor" transfer RNA (tRNA) that inserts a serine at the UAG codon.[200] Several other nonsense mutations causing thalassemia have been described (Fig. 21-12; see also Table 21-2).[158,171,201-205] In addition, single or dinucleotide insertions or deletions have been observed that alter the translational reading frame and introduce a premature stop codon as a consequence.[3,148,169,172,180,206-214] Two termination mutations have been described in the α-globin genes, one that introduces a stop codon[215] and the other a frameshift.[205] In addition, frameshift mutations have been described that result in abnormal elongation of globin chains (see the section on unstable β-globin chains).

mRNA molecules with termination mutations often do not accumulate to a normal level in vivo.[189,215] The extent of this effect is variable and depends on the specific mutations; deletion of the third nucleotide (C) from codon 41 (Fig. 21-13) leads to complete absence of globin mRNA,[216] whereas a single substitution in the β39 codon allows the accumulation of roughly 5% to 10% of the normal amount of globin mRNA.[215] The basis for the quantitative deficiency in these mRNA species is of considerable interest. Some data suggest that such mutations lead to

Figure 21-11 Two of the several thalassemia mutations that destroy gene function by the introduction of a premature translation termination codon in β-globin messenger ribonucleic acid (mRNA). The numbers above the individual codons refer to the position of the encoded amino acid in the β-globin. Replacement of C with T in codon 39 introduces the terminator UAG in β-globin mRNA. Another β^0 gene has a deletion of the third nucleotide (C) in codon 41, which results in a shift in the reading frame of the mRNA; the new amino acid sequence is shown above the line. This new reading frame has an in-phase terminator (UGA) in a position corresponding to codon 60 to 61. *(Modified from Nienhuis AW, Anagnou NP, Ley TJ: Advances in thalassemia research.* Blood *63:738–758, 1984.)*

intranuclear degradation of abnormal globin RNA and suggest a link between mRNA translation and nuclear RNA processing or nuclear to cytoplasmic transport of mRNA.[217,218] Experimental studies in tissue culture systems have shown that the deficiency in β-globin mRNA accumulation is specific for nonsense mutations and is not observed with missense mutations[198]; a suppressor tRNA that allows the abnormal mRNA molecule to be translated completely will correct the quantitative deficiency in globin mRNA.[218] Recent work from a number of investigators has begun to unravel the molecular machinery that mediates this phenomenon, which has been termed *nonsense-mediated decay*, and appears to play an important role in normal physiology, as well as pathologic states.[219]

Termination Codon Mutations

UAA is the normal termination codon for both α- and β-globin mRNA translation. The 3′-untranslated regions are 109 and 132 nucleotides for α- and β-globin mRNA, respectively. A single nucleotide substitution in the termination codon could either create another stop codon (UAG) or permit incorporation of an amino acid at this position and translation of the otherwise untranslated 3′ sequences until the next in-frame stop codon. Four termination codon mutations involving the α_2 gene have been reported (see Table 21-2).[220-225] These mutants differ only in the specific amino acid incorporated at the terminator codon position (see Fig. 21-13). Translation terminates in each instance at a UAA codon in the

Figure 21-12 Ribonucleic acid cleavage and polyadenylation occur 15 to 20 bp downstream from the AAUAAA polyadenylation signal. Mutational analysis in the rabbit β-globin gene has established that sequences located downstream from the polyadenylation site, called the G/U cluster, are also required for efficient cleavage and polyadenylation. Individual point mutations at one of several nucleotides within the AAUAAA polyadenylation signal result in β^+-thalassemia. The same A→G mutation in the last position that causes β-thalassemia has been observed in the α_2-globin gene and results in α^+-thalassemia.

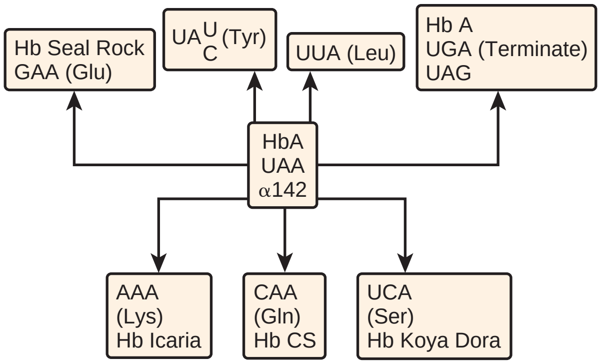

Figure 21-13 Point mutations in the terminator codon of the α-globin gene that lead to the synthesis of elongated α-globins. The normal terminator, UAA, of α-globin messenger ribonucleic acid is shown in the center. Each of the nine possible single nucleotide substitutions is depicted; two would result in the formation of another terminator codon, whereas the other seven would lead to insertion of an amino acid at this position and continued synthesis of the globin chain. Four such mutations have been described; the mutation that causes the synthesis of hemoglobin (Hb) Constant Spring (CS) is the most common. *(Modified from Weatherall DJ, Clegg JB:* The thalassemia syndromes. *Oxford, 1981, Blackwell Scientific, p. 578.)*

polyadenylation signal (AA*UAA*A) downstream, and a 172–amino acid polypeptide is produced. The first of these elongated α chains to be described was found in Hb Constant Spring (CS).[220,221] The α chain in this hemoglobin has a glycine substituted at codon 142. Hb CS produces an associated thalassemia phenotype because of a marked reduction in α_2-globin mRNA stability.[226-228]

Mutations that give rise to elongated β-globin chains have also been described. Hb Tak is a 157–amino acid product of a β-globin mRNA molecule containing two inserted nucleotides in the terminator codon 147.[225] An analogous elongated β-globin with 157 amino acids found in Hb Cranston reflects a dinucleotide insertion in codon 147, but red blood cells containing Hb Cranston are morphologically normal.[229] The mechanism by which the β^{Tak} mutation causes thalassemia has not been elucidated.

Mutations Affecting Globin Chain Stability

Hemoglobin Assembly. Shortly after synthesis is completed, α- and β-globin chains bind a heme moiety and rapidly associate into $\alpha_1\beta_1$ dimers in a noncovalent reaction that is nearly irreversible under physiologic conditions.[230] The majority of the heme contact points are present in the portion of the globin chains encoded by exon 2, whereas most $\alpha_1\beta_1$ contacts are located within the exon 3 domain (Fig. 21-14).[6,231] These dimers may then reversibly associate with other dimers to form the hemoglobin tetramer. Formation of the $\alpha_1\beta_1$ dimer, therefore, is the principal controlling step in the assembly of hemoglobin. This subject is discussed in greater depth in Chapter 19.

Hemoglobin assembly is an important determinant of the final hemoglobin composition of the erythrocyte.[230,232,233] The rate constant of dimer formation depends greatly on the surface electrostatic charge of the subunits.[230] α-Globin has a net positive surface charge, whereas β-globin has a net negative surface charge. The other normal β-like globin chains, γ-globin and δ-globin, dimerize with the α chain at a lower rate. δ-Globin has a lower net negative surface charge than does β-globin, and the significant structural differences between γ- and β-globin presumably account for the differing dimerization rates. When β-globin chains are in limited supply (i.e., β-thalassemia), HbA_2 and HbF levels may increase because of enhanced dimerization with α chains, independent of changes in the production of δ and γ chains. In α-thalassemia or iron deficiency, HbA_2 and HbF levels will decrease because of competition with β chains for the limited number of α chains. Similarly, β-chain variants may have decreased (β^S and β^E) or increased ($\beta^{Baltimore}$) affinity for α chains based on their net surface charge. The net hemoglobin composition of the cell is determined by these simple rules of competition based on the relative affinity of hemoglobin subunits.

An efficient, energy-dependent protein quality control system is present in erythrocytes that rapidly degrades free globin chains while leaving chains that are incorporated into dimers or tetramers unaffected.[230,234,235] Changes in globin chain structure that result from amino acid substitutions, premature chain termination, or chain elongation may slow or block the formation of stable $\alpha_1\beta_1$ dimers and lead to rapid degradation of the globin chain. In some instances, as discussed later, mutations may also enhance association of the free globin chain with the cell membrane and thereby promote oxidative damage to the membrane and shortened red blood cell survival.

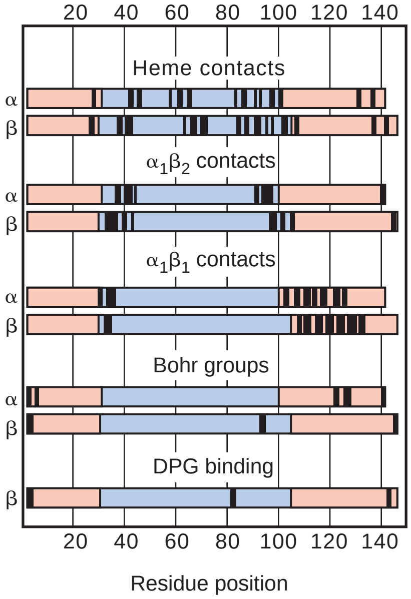

Figure 21-14 Schematic representation of the α- and β-globin chains and the location of residues involved in different hemoglobin functions (*black vertical bars*). Heme contact sites and $\alpha_1\beta_2$ contacts are concentrated in the second exon (*blue*), whereas $\alpha_1\beta_1$ contacts are principally located in the third exon (*salmon*). *DGP,* Diphosphoglycerate. *(Modified from Eaton WA: The relationship between coding sequences and function in haemoglobins.* Nature *284:183–185, 1980.)*

An erythroid-specific α-hemoglobin–stabilizing protein (AHSP) acts as a chaperone for free α-globin chains. In the absence of this protein, mice exhibit mild hemolytic anemia as a result of α-globin precipitation.[236] When this protein is absent in the presence of a β-thalassemia mutation in mice, a much more severe thalassemic phenotype occurs.[237] However, it is currently unclear whether variation in the structure or expression of this gene in humans causes phenotypic variability in patients with β-thalassemia. One study has suggested that this was not the case in patients with HbE–β-thalassemia in Thailand.[238] Another study has suggested that expression levels of this gene vary in humans and that such levels may correlate with the severity of β-thalassemia.[239] Further studies will need to be conducted to better understand whether AHSP plays a role as a modifier gene in β^+-thalassemia.

During hemoglobin biosynthesis it is also important that the globin chains not be produced in excess of heme. A protein called heme-regulated inhibitor (HRI) kinase appears to mediate this function by inhibiting globin chain translation when an erythroid precursor is deficient in heme.[240] When HRI is absent in mice with a β-thalassemia mutation, the thalassemic phenotype is exacerbated and lethality of the mice results.[241]

Unstable α-Globin Chains. One such unstable variant was identified on sequencing of a mutant α-globin gene (see Table 21-2).[242] The $\alpha^{\text{Quong Sze}}$ variant, which contains a Leu→Pro substitution at position 125, is so unstable that the mutant globin chain cannot be detected by biosynthetic studies in intact cells or by conventional hemoglobin electrophoresis.[243] The $\alpha^{\text{Quong Sze}}$ chain appears to be stable once it is incorporated into the hemoglobin tetramer. Three other similar unstable α-globin chain mutations have been described (see Table 21-2).[244-247]

Unstable β-Globin Chains

Several unstable β-globin chains have been associated with thalassemia (see Table 21-2). Five mutations lead to amino acid substitutions in the β-globin chain.[248-252] Frameshift mutations in the third exon result in the synthesis of an elongated β-globin chain with a novel carboxyterminal.[3,251,253-257] A premature termination mutation in exon 3 has also been described.[255-257] Many of the unstable β-globin chain mutations in exon 3 are associated with a dominantly inherited form of thalassemia (see the section on dominant β-thalassemia).[251,252] Thein and colleagues[255] proposed that alterations in β-globin structure in exon 3 interfere with $\alpha_1\beta_1$ dimer formation yet may permit binding of heme to the mutant globin chain through contacts in the exon 2 domain. These free, heme-associated β chains may be more resistant to proteolysis and associate with the cell membrane, where they form "inclusion bodies" and induce oxidative damage.

Thalassemic Hemoglobinopathies

The mutations described in this section, taken together with the RNA-processing mutants HbE, Hb Knossos, and Hb Malay and the termination mutant Hb Tak, include a distinctive set characterized by structural changes in the hemoglobin molecule and a thalassemia phenotype. These mutations are often referred to as "thalassemic hemoglobinopathies" (see the section on thalassemic hemoglobinopathies)[258] and are characterized clinically by a syndrome of ineffective erythropoiesis. Other globin variants may be associated with mild hypochromia, microcytosis, and chronic hemolysis because of instability and degradation of hemoglobin tetramers and are discussed in detail in Chapter 19. Because thalassemia is the consequence of an imbalance in α- and β-globin chains, these variants are not considered part of the spectrum of thalassemia.

Identification, Characterization, and Ethnic Distribution of β-Thalassemia Mutations

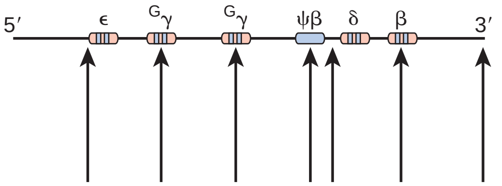
The hemoglobin disorders serve as a paradigm for the molecular analysis of genetic disease. Study of β-thalassemia was aided by the introduction of methods for identifying and characterizing mutant alleles that are now widely used. Accordingly, the identification of β-thalassemia mutations in many ethnic groups is nearly complete.[3,161]

In this section we briefly outline molecular techniques that have been applied to the characterization of β-thalassemia mutations. An understanding of these methods is important not only because they are broadly used in the study of other genetic diseases but also because they are directly relevant to strategies for genetic screening and prenatal diagnosis of β-thalassemia.

Haplotype Analysis

The first several β-thalassemia mutations were identified by cloning and sequencing β-globin genes isolated from persons with β-thalassemia major.[162,181,182,199,203,214,259-263] Because certain mutations are extremely common, a nondirected strategy is inefficient because β genes with common mutations will be repeatedly studied. For example, 95% of the β-thalassemia alleles on the island of Sardinia contain the codon 39 nonsense mutation.[264]

To facilitate the search for new β-thalassemia mutations, Orkin, Kazazian, Kan, and others[149,265,266,268] introduced the concept of haplotype analysis to the study of thalassemia. Naturally occurring, genetically neutral, nonselected sequence differences among individuals constitute polymorphisms, which are estimated to occur roughly once every 100 bp.[267] These sequence differences are heritable, and those residing close to one another on a chromosome tend to be inherited together, a property known as *linkage*. A subset of polymorphisms will alter the cleavage site for a restriction enzyme or create a site where one did not exist. Therefore, when DNA from unrelated individuals is digested with a restriction enzyme and analyzed by Southern blotting, polymorphisms in the restriction enzyme digest pattern may be observed and are referred to as restriction fragment length polymorphisms (RFLPs).[268] Within the 60 kb of the human β-globin cluster, more than such 20 RFLPs are known[5,269]; at least 13 have been identified in the α cluster.[2,270] The pattern of these RFLPs (each based on the presence [+] or absence [–] of a restriction enzyme cutting site) along the chromosome defines a haplotype of associated or linked polymorphisms. Seven RFLPs were used initially to define nine distinct haplotypes (I through IX) of the



Haplotypes	Hinc II	Hd III	Hd III	Hinc II	Ava II	Bam HI	Mutation	Overall frequency
I	+	–	–	– –	+	+	IVS-I n. 110	47%
II	–	+	+	– +	+	+	Codon 39	17%
III	–	+	–	+ +	+	–	IVS-2 n. 1	8%
IV	–	+	–	+ +	–	+		1%
V	+	–	–	– –	+	–	IVS-In. 1 (G→A)	12%
VI	–	+	+	– –	–	+	IVS-I n. 6	6%
VII	+	–	–	– –	–	+	IVS-2 n. 745	6%
VIII	–	+	–	+ –	+	–	–87	1%
IX	–	+	–	+ +	+	+	Codon 39	3%

Figure 21-15 Linkage of chromosomal haplotypes to specific β-thalassemia mutations in Mediterranean populations. A haplotype is defined by the sequential pattern of restriction enzyme sites (present "+" or absent "–") along a chromosome. In this example, seven restriction enzyme sites were used to classify nine haplotypes. Overall frequency refers to the prevalence of the specific haplotype as found in all persons, with or without thalassemia. *IVS,* Intervening sequence. *(Modified from Orkin SH, Kazazian HH Jr, Antonarkis SE, et al: Linkage of beta thalassaemia mutations and beta-globin gene polymorphisms with DNA polymorphisms in the human beta-globin gene cluster.* Nature *296:627–631, 1982.)*

β-gene cluster in the analysis of thalassemia mutations in Greek and Italian populations from the Mediterranean basin (Fig. 21-15).[149]

Close inspection of these haplotypes revealed a nonrandom association of restriction digest patterns within the β-gene cluster (Fig. 21-16).[265,271] The pattern of restriction sites 5′ of the δ-globin gene is inherited as a group, whereas restriction sites downstream (including the β-globin gene) track as another set. In all populations only a few haplotypes predominate.[272] The full spectrum of haplotypes is derived from random association over evolutionary time between the 5′ and the 3′ subhaplotypes, presumably reflecting the presence of a recombination "hot spot" lying between these regions.[162,271,273,274]

The generation of haplotypes appears to be an ancient event predating racial dispersion. Consequently, a specific haplotype may be found in diverse ethnic and racial groups from different geographic locations. The introduction of malaria as a selective pressure for certain random mutations is a more recent phenomenon. A mutation leading to thalassemia would be under positive selection and amplified within a population; accordingly, the mutation resides on the haplotype background in which it originated in that ethnic group. Several conclusions were derived from the study of different racial groups.[106] Within a single population both normal and thalassemia β-globin genes are found on the same haplotype, but specific thalassemia mutations tend to be linked to a single haplotype. Individual thalassemia mutations are generally restricted to a single population (see Table 21-2). In circumstances in which specific mutations are found in different populations, the identical thalassemia mutation may have occurred and been selected independently and will be found on a different haplotype background.[47,167,275] This observation has provided a sound genetic basis for the belief that thalassemia has had multiple distinct origins throughout the world. In circumstances in which a specific mutation is found on more than one haplotype within a population, the 3′ subhaplotypes (where the β-globin gene resides)

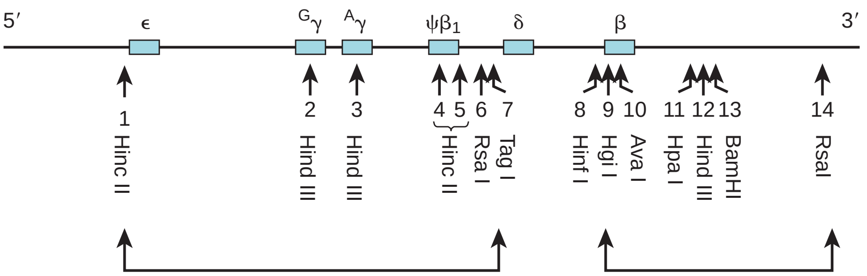


Figure 21-16 Restriction endonuclease sites for which restriction fragment length polymorphisms (RFLPs) have been identified in the β-globin gene cluster. A recombinational hot spot has been identified between the two brackets; the RFLP enclosed in each bracket must often remain associated during recombination (see text).

may be identical, whereas the 5′ subhaplotypes differ because of recombination between the two subhaplotypes (for an example, see codon 39 mutation, see Fig. 21-15). By this mechanism, specific mutations can be distributed to new haplotypes within an ethnic group, and an independent origin of the mutation need not be invoked.

New thalassemia mutations were identified by cloning thalassemia β-globin genes from distinct haplotypes within a population, thereby avoiding the likelihood of repeated cloning of the same common mutation.[149] In this way, the great diversity of thalassemia mutations was elucidated.[164]

Ethnic Distribution

Determining the incidence of specific β-thalassemia mutations in different ethnic groups is particularly relevant to strategies for prenatal diagnosis of or preconception screening for thalassemia.[3] Nearly complete surveys of thalassemia mutations have been performed in Greek and Italian,[266] Asian Indian,[154,276] American black,[43,171] Sardinian,[264] Chinese,[277,278] Lebanese,[155] Turkish,[279] Spanish,[280] Sicilian,[281] Thai,[201] Kurdish Jewish,[148] and Japanese[252] populations. From these studies, several general conclusions can be drawn. First, in each ethnic group a small subset of mutations (as few as four or six) constitute more than 90% of the mutant alleles. This characteristic is particularly striking on the island of Sardinia, where the codon 39 nonsense mutation accounts for 95% of the β-thalassemia genes and a codon 6 frameshift represents another 4%.[264] Second, the remaining 5% to 10% of mutant alleles in an ethic group are divided among a larger number of rarer alleles. For example, four alleles account for 90% of the β-thalassemia genes in Chinese, and 11 rare alleles account for the remaining 10%.[3,277] Third, several mutations appear to have originated independently in different ethnic groups and are present on different haplotype backgrounds, as discussed earlier. For example, the IVS-2 No. 1 (G→A) mutation is present in Mediterranean, Tunisian, and American black populations,[159,161,163] whereas the IVS-1 No. 5 (G→C) substitution is present in Asian Indians, Chinese, and Melanesians.[131,158,169] Finally, as a consequence of the large number of mutations present in each population, most persons with severe β-thalassemia are genetic compound heterozygotes for two different thalassemia mutations.

Mutations That Affect β-Globin Gene Regulation

Deletions within the β-globin gene cluster often lead to thalassemia. Many of these deletions are associated with a significant increase in the level of HbF, a finding that distinguishes them from the common varieties of β-thalassemia. Ordinarily, heterozygous carriers of β-thalassemia have an increase in the level of HbA_2 (to >3% of total hemoglobin) and, at most, a slight increase in the level of HbF. Before detailed molecular analysis was available, these conditions were broadly grouped into two categories, hereditary persistence of fetal hemoglobin (HPFH) and δβ-thalassemia[4,282,283] (Table 21-3). HPFH heterozygotes have normocytic, normochromic red blood cells, whereas δβ-thalassemia heterozygotes have hypochromic and microcytic cells. Many HPFH heterozygotes have high levels of HbF (up to or greater than 30%) with a uniform or pancellular distribution in circulating erythrocytes, whereas in δβ-thalassemia heterozygotes, the amount of HbF is less abundant and it is present in an uneven or heterocellular distribution among red blood cells. In rare persons who are homozygous for either condition, only HbF is found. HPFH homozygotes have normal or slightly elevated total hemoglobin concentrations, their red blood cells are slightly hypochromic and microcytic, and globin synthesis is modestly imbalanced.[284,285] Thus these mutations are appropriately considered along with the thalassemia mutations.

TABLE 21-3 Phenotypes of $^G\gamma^A\gamma$ Hereditary Persistence of Fetal Hemoglobin and $^G\gamma^A\gamma\ (\delta\beta)^0$-Thalassemia Heterozygotes

Deletion mutations of the β-globin gene cluster represent in vivo experiments of nature useful in developing and validating experimental models of gene regulation. Multiple regulatory elements are present within the cluster, and the clinical phenotypes observed with specific deletions relate to removal of one or more such regulatory elements. More than 30 deletion mutations have been described (Table 21-4 and Fig. 21-17)[286]; they vary greatly in size from a few hundred base pairs of the β-globin gene to more than 100 kb with loss of the entire cluster. Recent studies have shown how insight from such deletions and mapping regions that diverge between the HPFH and δβ-thalassemia deletions can help to elucidate key regulatory regions important for HbF expression.[93] For example, a region upstream of the δ-globin gene has been implicated in playing a key role in silencing the γ-globin genes and binds the HbF silencing factor BCL11A. In addition to deletion mutations, significant elevations of HbF in adults may arise as a result of single base substitutions within the γ-globin gene promoters (Table 21-5). Such mutations, also classified as nondeletion HPFH, appear to enable the γ-globin genes to "capture" the influence of the LCR at the adult stage. Persons with these HPFH mutations have HbF values ranging from only slightly elevated to more than 20%, which can be distributed in either a heterocellular or pancellular fashion.

HPFH and δγ-thalassemia mutations are uncommon, and persons who inherit these mutations are asymptomatic or have mild disease. Their importance relates to the insight that they provide into globin gene regulation and

the role of HbF in modulating disease severity in patients with severe γ-thalassemia or sickle cell anemia.

Isolated point mutations of the δ-globin gene, similar to those in β-thalassemia, may lead to "δ-thalassemia." δ-Thalassemia is a benign condition with no clinical significance that, when inherited with a β-thalassemia mutation, may lead to a normal or low HbA_2 thalassemia phenotype in heterozygotes.[287,288]

Crossover Globins: Hemoglobin Lepore and Hemoglobin Kenya

Deletion mutations in the α- and β-globin gene clusters arise through unequal homologous recombination or through nonhomologous (illegitimate) recombination. In contrast to the α-globin cluster, in which there are blocks of tandem duplicated sequences (discussed later), the only directly repeated homologous segments of DNA in the β

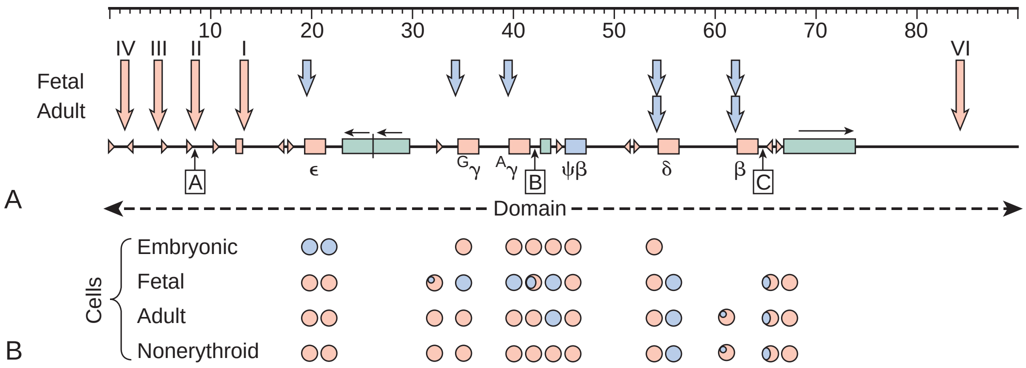

Figure 21-17 **A,** Organization and chromatin structure of the human β-globin cluster. The expressed genes are shown as *salmon boxes* and the single pseudogene in the cluster as a *blue box*. The *arrowheads* in the line figure indicate the location and orientation of Alu repetitive deoxyribonucleic acid (DNA) sequences, whereas the *green boxes* represent members of the L1 family of repetitive DNA. The *salmon downward arrows* mark developmentally stable, erythroid-specific hypersensitive sites that constitute the locus-activating region (LAR) flanking the cluster. The true boundaries of the "active" chromatin domain established by these sites are unknown and extend beyond the cluster. Hypersensitive sites are also found over the promoters of the expressed genes (*blue downward arrows*). The location of the three enhancers in the cluster are marked by letters: A, hypersensitive site II enhancer; B, 3′ $^A\gamma$ enhancer; C, 3′ β enhancer. **B,** The methylation pattern of the locus at different stages of ontogeny is depicted. *Blue circles* show an unmethylated site, *salmon circles* show a totally methylated site, and *circles with blue and salmon* show the degree of site methylation. The coordinates refer to distance in kilobases. *(Modified from Stamatoyannopoulos G, Nienhuis AW: Hemoglobin switching. In Stamatoyannopoulos G, Nienhuis AW, Leder P, Majerus PW, editors:* The molecular basis of blood diseases, *Philadelphia, 1987, WB Saunders, p. 79.)*

cluster are the globin genes themselves. Hence mutations arising from homologous but unequal crossover in the β-globin cluster are relatively uncommon and usually involve two globin genes directly (Fig. 21-18). Two crossover hemoglobins, Hb Lepore and Hb Kenya, are associated with thalassemia.

In 1958, Gerald and Diamond[289] identified a minor hemoglobin component by starch gel electrophoresis in the blood of parents of a patient with thalassemia major. Structural analysis revealed that the hemoglobin was composed of α-globin and a heretofore undescribed globin consisting of fusion of the 80 to 100

amino-terminal amino acids of δ-globin with the carboxyl portion of β-globin.[290-293] This "chimeric" globin polypeptide, named Lepore after the family in which it was first described, arose from an unequal, homologous recombination event between the δ-globin and β-globin genes (Fig. 21-18). It is poorly expressed because transcription of the fusion gene is under control of the δ-gene promoter. Other Lepore-type globins have been characterized in which the relative contribution of the δ and β genes to the fusion protein varies as a result of a different point of crossover. Homozygotes for Hb Lepore have 90% HbF and approximately 10% Hb Lepore, but no HbA or HbA$_2$, whereas heterozygotes have mainly HbA, 2% to 4% Hb Lepore, and 3% to 5% HbF.[294,295] In heterozygotes, red blood cells have a very heterogeneous HbF content. Anti-Lepore globins with the amino-terminal sequence of β-globin and the carboxyl sequence of δ-globin have also been described (see Fig. 21-18).[296-299] Persons with anti-Lepore genes also have two normal δ- and two normal β-globin genes; consequently, their red blood cells lack any stigmata of thalassemia. The anti-Lepore globins are produced in very low amounts, perhaps because of sequences within the large intron of the δ-globin gene that may reduce mRNA production.[26]

Hb Kenya, another important crossover hemoglobin, contains a non–α-globin composed of amino sequences of γ-globin and carboxyl sequences of β-globin[300-303] (see Fig. 21-18). Molecular analysis demonstrated that the $^{A}\gamma$-globin gene was involved in the crossover. The crossover occurred approximately at the position of amino acid codon 100. Hb Kenya was first observed in an individual who was heterozygous for a β^{S} gene. This patient had an increased level of HbF (up to 6%) that was uniformly distributed in all his red blood cells. The HbF was entirely of the $^{G}\gamma$ type. Hb Kenya accounted for 17% to 20% of the total hemoglobin. Persons who are heterozygous for Hb Kenya without HbS are clinically healthy. Approximately 10% Hb Kenya and 6% to 10% HbF of the $^{G}\gamma$ type are found homogenously distributed in their red blood cells, in contrast to the distribution of HbF with the Lepore-type deletion.[302]

Silent Deletions

Deletions that eliminate a single γ-globin gene or the δ-globin gene are unlikely to result in a phenotype that would be detected in hematologic screening, and thus few of these mutations have been detected and described. A clinically silent deletion of the $^{A}\gamma$-globin gene was identified through extensive molecular screening of chromosomes in Melanesians.[304] A 7.2-kb deletion involving the δ-globin gene but not the γ- or β-globin gene was reported in Corfu $(\delta\beta)^0$-thalassemia in *cis* to the G→A substitution at IVS-1 position 5.[305] Homozygotes for the IVS-1 position 5 mutation ordinarily exhibit a mild β+-thalassemia intermedia phenotype with 10% to 20% HbA,[172] but homozygotes for Corfu $(\delta\beta)^0$-thalassemia display the clinical phenotype of β^0-thalassemia intermedia with 100% HbF. This finding has been interpreted as evidence that sequences in the deleted region are important in activating the β-globin gene and potentially in suppressing γ-gene expression. Subsequently, however, the identical deletion was identified in *cis* to a normal β-globin gene.[306] In this circumstance, the deletion leads to failure of δ-globin gene expression but has no demonstrable effect on expression of the γ- and β-globin genes on the same chromosome. Recent work has suggested that this deletion may increase γ-gene expression in *cis* to the deletion but that translation of the γ gene may be limiting in certain settings, thus helping explain the discrepancy between carriers of the deletion and homozygotes.[307] The previously discussed mapping studies of HPFH and δβ-thalassemia deletions suggest that the regulatory element upstream of the δ-globin is important for γ-globin silencing, consistent with the idea that the Corfu deletion is removing this critical regulatory element and therefore can result in elevated HbF levels.[93,308]

β^0-Thalassemia Deletion Mutations

Several deletions remove the β-globin gene and are associated with typical high-HbA_2 β^0-thalassemia (see Table 21-4). Interestingly, deletions that remove the promoter region are associated with somewhat higher HbF levels than usually seen in β^0-thalassemia heterozygotes (e.g., see Oner and colleagues[309]). The HbF is distributed in a heterocellular pattern. In contrast, a 0.6-kb deletion at the 3′ end of the β gene that spares the β-globin promoter, seen in Asian Indians, is not associated with an increased level of HbF in heterozygotes.[158,260-262,310] One explanation for the different phenotypes relates to the possibility that an intact β-gene promoter may interact productively with the LCR and thereby effectively compete with an incompletely silenced γ-globin gene at the adult stage. Removal of the promoter may alleviate competition and favor persistent γ-globin expression.

δβ-Thalassemia

Persons heterozygous for these deletions generally have 5% to 20% HbF composed of both $^G\gamma$- and $^A\gamma$-globins and distributed in a heterocellular fashion (see Table 21-4). The erythrocytes are typically hypochromic and microcytic.[1] The level of HbA_2 is characteristically low in comparison with the modest elevations observed in most persons with β-thalassemia trait. Homozygotes for these deletions produce only HbF yet exhibit a mild β^0-thalassemia intermedia phenotype with hemoglobin levels of approximately 10 g/dL. The most common of these deletions is referred to as the Sicilian type.[311-314] The deletion extends from within the δ-globin gene to just beyond the β-globin gene (see Table 21-4). As previously discussed, recent work comparing such deletions with the similar HPFH deletions has provided insight into potential regulatory regions needed for HbF silencing and which are bound by the critical HbF silencing factor, BCL11A.

$^A\gamma\delta\beta$-Thalassemia

The phenotype of these deletions in heterozygotes is identical to that of δβ-thalassemia: hypochromic microcytic red blood cells with low levels of HbA_2 and moderately increased $^G\gamma$-HbF levels (5% to 15%) with a heterocellular distribution (see Table 21-4). Homozygotes have β^0-thalassemia intermedia with 100% $^G\gamma$-HbF. The 5′ breakpoints in these instances lie between the two γ genes or within the body of the $^A\gamma$ gene, thereby resulting in silencing of the $^A\gamma$ gene together with the δ and β genes.[315-324] The 3′ end points of several of these deletions have been precisely mapped. Other deletions are very large and extend well beyond the boundary of the β-gene complex (see Table 21-4). One interesting mutation of this type, the Indian form (see Table 21-4), has two deletions, one involving the γ gene and the second involving a portion of the δ and β genes and intragenic DNA. The segment of DNA between the two deletions is inverted such that the 5′ ends of the γ and δ genes come to be adjacent but in an inverted orientation.[315,316]

γδβ-Thalassemia

The diagnosis of γδβ-thalassemia should be considered in newborns with hemolytic disease associated with hypochromic red blood cells. In adults, it is also a cause of normal-HbA_2, normal-HbF β-thalassemia trait. The syndrome was first identified in a newborn with microcytic, hemolytic anemia.[325] Heterozygous β-thalassemia associated with normal levels of HbA_2 and HbF was identified in the father and many relatives. Decreased γ- and ββ-chain synthesis was demonstrated in the infant's reticulocytes. The anemia was self-limited; as the baby grew older, the hemolytic anemia disappeared and the phenotype of simple heterozygous β-thalassemia developed in the child.

The syndrome of γδβ-thalassemia results from large deletions within the β-globin gene cluster (see Table 21-4). They can be divided into two categories: extremely large deletions that remove the entire β-globin gene cluster or all of the structural genes[326-328] and deletions such as the Hispanic, English, Dutch, and Anglo-Saxon forms in which the structural genes are left intact but the LCR elements are removed.[319,329-334] The remaining genes on the chromosome are not expressed and are found in inactive chromatin that is methylated and resistant to nuclease digestion. Study of these deletions has provided the most convincing evidence that the LCR is required in normal erythroid cells for transcription of the β-like globin genes in vivo. Homozygous γδβ-thalassemia is expected to be incompatible with survival and has not been observed.

β-Thalassemia Mutants Unlinked to the β-Globin Complex

Until recently, the mutations characterized in β-thalassemias resided within or near the β-globin gene itself or the β-globin locus. In principle, defects in *trans*-acting regulatory factors could lead to failure of proper β-globin gene expression. Two examples are now known.

Mutation of the xeroderma pigmentosum disease (XPD) helicase gene, which encodes a component of the general transcription factor TFIIH, results in β-thalassemia in association with trichothiodystrophy. Patients with specific mutations in *XPD* have typical features of β-thalassemia trait, including reduced levels of β-globin synthesis. Inadequate expression of diverse, highly expressed genes is presumed to be the direct consequence of an abnormality in TFIIH.[335]

Mild β-thalassemia trait in association with thrombocytopenia was reported as an X-linked trait in a rare family.[336] Linkage studies demonstrated that the gene mutated in this family resides on the short arm of the X chromosome, near the Wiskott-Aldrich syndrome (*WAS*) gene and the erythroid/megakaryocytic transcription factor GATA1.[337] Subsequently, it was shown that affected boys in this family have a specific amino acid substitution in the amino zinc finger of GATA1 that subtly alters its interaction with DNA and leaves its physical interaction with the cofactor FOG-1 intact.[58] How this change in the properties of GATA1 leads to a slight imbalance in globin gene expression is unknown, although it has been suggested that this mutation may disrupt interactions of GATA1 with other erythroid transcription factors such as TAL1.[338] More recently, similar mutations have been found in other patients. In one case, β-thalassemia was present along with an elevation in HbF to nearly 60%.[56] This patient also had features of erythropoietic porphyria and mild thrombocytopenia. However, another patient with a similar mutation had features of only gray platelet syndrome, and β-thalassemia was not present.[57] These phenotypic differences may be due to differential effects on the TAL1 complex to which GATA1 binds.[338]

Hereditary Persistence of Fetal Hemoglobin

Persons who are heterozygous or homozygous for mutations that enhance HbF are asymptomatic. They are identified incidentally in routine screening programs or during investigation of family members with hematologic disease because of interaction of these variants with other mutations in the β-globin gene cluster. Homozygotes for deletion forms of HPFH have normal hemoglobin concentrations, but their red blood cells are slightly hypochromic and microcytic.[284,285] Minimal globin chain biosynthetic imbalance may be seen. No symptoms or physiologic impairment has been associated with the exclusive production of HbF despite its high oxygen affinity.

Hereditary Persistence of Fetal Hemoglobin Deletion Mutations

Several deletions produce the HPFH phenotype of increased levels of HbF in otherwise normal red blood cells (Table 21-5).* Heterozygotes for these deletions can produce greater than 30% HbF containing both $^G\gamma$ and $^A\gamma$ chains in a pancellular distribution. Differences in the relative percentages of $^G\gamma$ and $^A\gamma$ chains can be detected between different types of HPFH deletions (see Table 21-4). Heterozygotes have normocytic red blood cells. The red blood cells of homozygotes contain HbF exclusively. The higher oxygen affinity of HbF may lead to slightly elevated hemoglobin levels in such individuals. Although homozygotes are clinically healthy, the α-globin to γ-globin chain biosynthetic ratio may be slightly imbalanced, and mild microcytosis and hypochromia may be observed. This finding suggests that γ-chain synthesis occurs at levels below the output of the normal β-globin gene on these chromosomes.

Several hypotheses have been put forward to account for the increased expression and pancellular distribution of HbF in the deletion HPFH syndromes, particularly when compared with the moderate increase and heterocellular distribution in δβ-thalassemia. As previously discussed, recent studies have examined the differences between several deletional forms of HPFH and δβ-thalassemia.[93] These studies have led to the identification of a region upstream of the δ-globin gene that appears to be a critical binding site for BCL11A and several partner proteins. This observation has also been substantiated through the analysis of the patients with deletional forms of β-thalassemia, where variation in the level of HbF expressed appears to be due to the presence or absence of this upstream region.[308] Further studies of this sort are needed to better understand the exact mechanisms by which this region acts to silence the γ-globin genes.[349]

Nondeletion Hereditary Persistence of Fetal Hemoglobin Mutations

Persons with nondeletion hereditary persistence of HbF mutations exhibit elevated levels of HbF with normal red blood cell indices and are identified through hemoglobin screening programs or by study of families in which a segregating high-HbF allele modulates the severity of sickle cell disease or β-thalassemia.[112,113] In many instances, single base changes have been discovered within the promoter region of either the $^G\gamma$- or $^A\gamma$-globin gene.[350-375] These mutations are postulated to alter the binding of nuclear regulatory proteins and lead to a more favorable interaction of the promoter with the LCR at the adult stage.[360,361,376-381] Alternatively, these mutations may disrupt the binding of repressor molecules that act to silence the expression of the γ-globin gene. Typically, only increased expression of the γ-globin gene in which the mutation is found occurs.

The level of HbF observed in patients with this syndrome varies greatly and ranges from a few percent to 30% in the −175 T→C substitution found in either the $^G\gamma$- or $^A\gamma$-globin gene.[362-364] Similar to the deletion forms of HPFH, the HbF may be found in either a heterocellular or a pancellular distribution (Table 21-6 and Fig. 21-19). The −158 C→T substitution in the $^G\gamma$-globin gene is associated with a normal level of HbF in otherwise normal heterozygotes but with a high level of HbF in the presence of erythropoietic stress.[366-372] For example, in Saudi Arabia, patients with sickle cell anemia often have high HbF levels (25% or greater) and mild disease, whereas their parents with sickle cell trait have normal or only slightly elevated levels.[366] Identification of persons with this mutation (or polymorphism) has been aided by the finding that it is linked to a rare subhaplotype.[367,369] The −158 HPFH substitution also improves the clinical course of β-thalassemia. A Chinese person homozygous for the −29 promoter mutation has transfusion-dependent β-thalassemia,[47] yet black patients homozygous for the same mutation who co-inherit the −158 HPFH mutation in the $^G\gamma$ promoter have mild β-thalassemia.[46,114]

Confirmation that the base substitutions in the promoter region are the cause of increased γ-chain synthesis

TABLE 21-6 α-Thalassemia Syndromes

Syndrome	Clinical Features	Hemoglobin Pattern	α-Globin Genes Affected by the Thalassemia Mutation
Silent carrier (α-thal-2)	No anemia, normal red blood cells	1%-2% Hb Bart's (γ_4) at birth; may have 1%-2% Hb Constant Spring; remainder HbA	1
Thalassemia trait (α-thal-1)	Mild anemia, hypochromic and microcytic red blood cells	5%-10% Hb Bart's (γ_4) at birth; may have 1%-2% Hb Constant Spring; remainder HbA	2
HbH disease	Moderate anemia; fragmented, hypochromic, and microcytic red blood cells; inclusion bodies may be demonstrated	5%-30% HbH (β_4); may have 1%-2% Hb Constant Spring; remainder HbA	3
Hydrops fetalis	Death in utero caused by severe anemia	Mainly Hb Bart's; small amounts of HbH and Hb Portland also present	4

Hb, Hemoglobin; *HbH,* hemoglobin H; *thal,* thalassemia.

rather than associated random DNA polymorphisms is based on several lines of evidence (reviewed by Ottolenghi and colleagues[382]). As mentioned earlier, they are generally associated with overexpression of the gene in which the mutation is found and typically represent the only sequence change. None of the mutations listed, with the exception of the −158 mutation, have been observed in persons with normal HbF levels. Haplotype analysis in some pedigrees of patients with HPFH has demonstrated that the HPFH determinant is linked to the β-globin cluster. The British type of nondeletion HPFH is quite informative in this regard. The gene has been tracked through three generations, and three homozygous individuals have been observed.[353-355,383] Haplotype analysis using restriction enzyme polymorphisms has established linkage of the British HPFH phenotype to the β-globin gene locus.[354] More than 90% of the γ chains are of the $^{G}\gamma$ type, and there is an associated mutation at −198 of the $^{G}\gamma$ gene.[354] Even the three homozygotes, with approximately 20% HbF, have heterogeneous distribution of HbF among their red blood cells. Two homozygotes for −117 $^{A}\gamma$ HPFH have also been described, and they had 24% HbF in a pancellular pattern.[384] More recent transgenic experiments provide support for the idea that the single base substitutions seen in HPFH can lead to enhanced γ-globin expression in adult life.

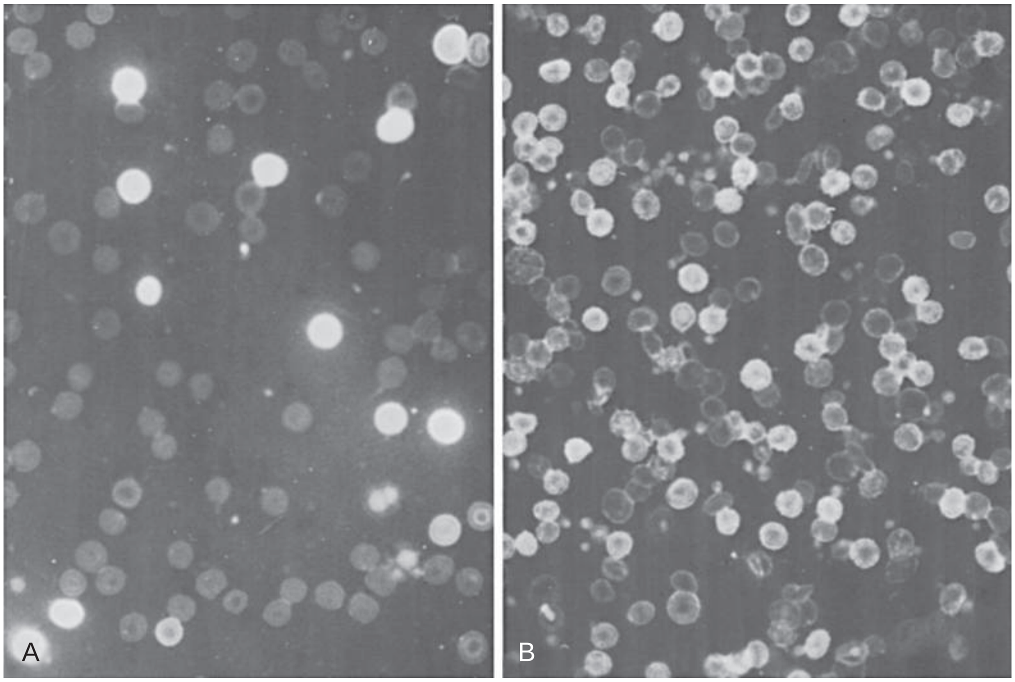

Figure 21-19 **A,** Immunofluorescent staining of erythrocytes with antibody directed against fetal hemoglobin (HbF) shows the distribution of HbF in a heterocellular pattern. **B,** Immunofluorescent staining of erythrocytes with HbF distributed in a pancellular pattern. *(Courtesy Dr. George Stamatoyannopoulos.)*

An interesting aspect of this syndrome is a balanced α-globin to non–α-globin chain synthetic ratio, even in homozygotes,[384] which implies that increased γ-globin synthesis is offset by decreased β-globin synthesis.[373] Expression of the β gene in *cis* to the mutation may be reduced by 20% to 30%.[350,363,364,374,385] It has also been observed that HbA_2 levels are uniformly low in the nondeletion HPFH syndromes and generally correlate inversely with HbF levels.[1] The reduction in δ- and β-globin gene expression in *cis* to the HPFH mutations is compatible with models of competitive regulation of β-globin expression by the linked γ-globin gene.

Mutations That Alter α-Globin Gene Regulation

In contrast to the β-globin cluster, in which single nucleotide substitutions are the most common cause of thalassemia, large deletions within the α-globin cluster are the predominant basis of α-thalassemia. The overall impairment in α-globin chain synthesis that results from defects in the α-globin cluster is determined by the number of genes inactivated (either by deletion or mutation), the type of lesion (deletion or mutation), and whether the lesion affects the α_2 or α_1 gene.

The α-globin cluster on chromosome 16[16,386,387] contains three functional genes (ζ, α_2, and α_1), an expressed gene of no apparent significance, and three pseudogenes[2,15] (see Fig. 21-2). Transcription of the genes depends on the integrity of the distant regulatory element HS-40. An α-thalassemia deletion mutation ($\alpha\alpha^{RA}$) has been reported that removes a large segment of DNA upstream of the ζ_2 gene but spares the remainder of the cluster.[388] In heterozygotes, no expression of the ζ- or α-globin genes from this chromosome is detected in heterozygotes. These findings are formally analogous to those in Hispanic and English γδβ-thalassemias (see Table 21-4),[329,330] in which upstream LCR elements of the β-globin cluster are deleted.

The two human α-globin genes are thought to have been generated through a gene duplication event that occurred approximately 60 million years ago.[389] The nucleotide sequences of the α_2 and α_1 genes have remained remarkably similar and represent an example of concerted evolution[390-392] in which the two genes have exchanged genetic information through crossover fixation and gene conversion events. The coding regions of the two genes are virtually the same and encode identical polypeptides.[390-393] The genes differ only in minor respects within IVS-2, whereas the sequences diverge significantly in the 3′-untranslated region.

The α-globin genes are expressed in embryonic, fetal, and adult-stage erythroid cells. Initially it was believed that the two α genes were expressed at similar levels, but subsequent RNA analysis relying on sequence differences in their 3′-untranslated regions revealed that α_2 RNA predominates over α_1 RNA by a ratio of 3:1.[226,394-396] Because the two α-globin mRNA molecules have the same intrinsic stability, the higher level of α_2 RNA reflects increased transcription of the α_2 gene. "Transcriptional interference" of the α_1 gene by the upstream α_2 gene has been proposed as an explanation for this observation.[397] Ribosome-loading studies suggest that α_2 and α_1 transcripts are translated at equivalent rates.[398] Systematic characterization of the expression of α-globin structural variants at both the α_2 and α_1 loci has confirmed that the α_2 gene has a predominant role in α-globin chain production.[394,395] A direct prediction of this model is that mutations altering the α_2 gene would result in a greater deficiency of α-globin chain production than would mutations of the α_1 gene. Clinical support for this prediction is provided by study of Sardinian patients with HbH disease who are heterozygous for one chromosome with a deletion of both α genes (–/) and a chromosome with a nondeletion mutation affecting the Inr codon of either the α_2 gene ($\alpha^T\alpha$/) or the α_1 gene ($\alpha\alpha^T$/).[194] Patients with the mutation in the α_2 gene (–/$\alpha^T\alpha$) have disease that is clinically more severe. Consistent with its predominance, the α_2 gene is involved in the majority of the reported mutations of the α-globin genes (see Table 21-2).

Deletion Mutations within the α-Globin Gene Cluster

Mutations That Remove One α-Globin Gene

The two α-globin genes are embedded in highly homologous, tandem repeated sequence blocks (called X, Y, and Z) that are separated by nonhomologous segments (Fig. 21-20).[18] Unequal, homologous recombination through the X and Z blocks generates a chromosome with a single α-globin gene and another with three α-globin genes. Homologous recombination in the small Y box has not been observed. The most common type of deletion in this class removes 3.7 kb as a result of misalignment of the Z boxes and is known as "rightward deletion." The products of this crossover are the ($-\alpha^{3.7}$/)[399,400] and ($\alpha\alpha\alpha^{anti\text{-}3.7}$/) haplotypes.[401,402] The $-\alpha^{3.7}$ products may be further subdivided into types I, II, and III by the precise location of recombination within the Z box.[392] Unequal crossover events through the X box leads to "leftward deletion" of 4.2 kb of DNA and the $-\alpha^{4.2}$ chromosome[382] and its triplicated antitype.[403,404] The incidence of the observed recombination products appears to reflect the size of the homologous target sequence within the boxes because $-\alpha^{3.7I}$ (1436 bp) is the most common, followed by $-\alpha^{4.2}$ (1339 bp), $-\alpha^{3.7II}$ (171 bp), and $-\alpha^{3.7III}$ (46 bp).[2,390,391,405] Unequal α-gene recombination through the X and Z boxes has been reproduced in both prokaryotic and eukaryotic experimental systems with episomal vectors.[18,406,407]

The $-\alpha^{3.7I}$ deletion is extremely common and is seen in all populations in which α-thalassemia is prevalent, whereas the $-\alpha^{4.2}$ deletion is most common in Asian populations.[2,15] Frequencies of up 80% to 90% for the single-deletion chromosome have been reported in some populations.[123] The association of these mutations with a variety of α-globin cluster haplotypes and α-globin variants in different populations suggests that they have arisen through numerous independent mutational events.[123,408]

Deletion of one α-globin gene does not affect expression of the ζ-globin gene[409] but has unanticipated consequences on expression of the remaining α-globin gene. The α_1 gene that remains on the $-\alpha^{3.7}$ chromosome is expressed approximately 1.8 times more often than the

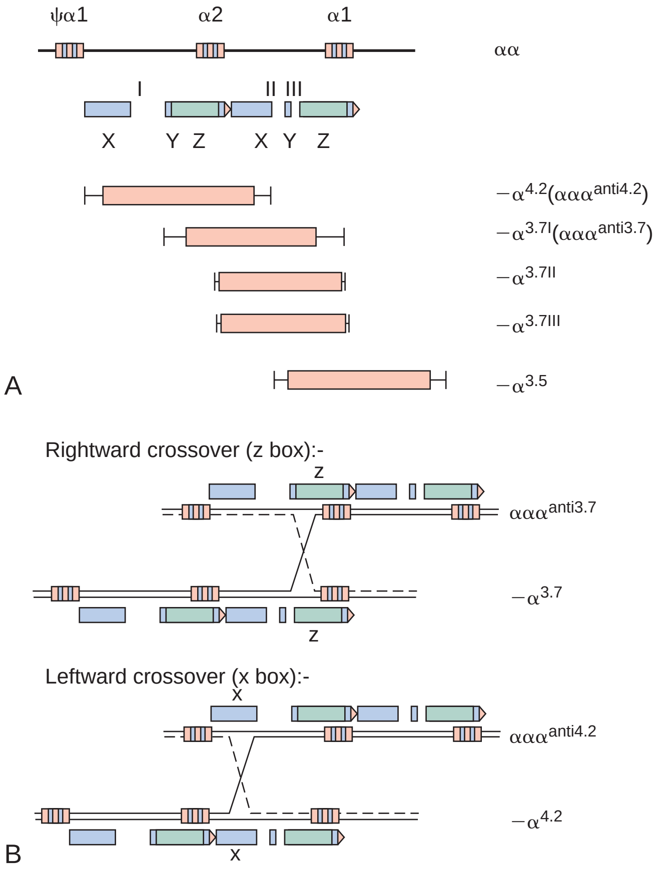

Figure 21-20 **A,** Deletion mutations that give rise to α-thalassemia. The two α-globin genes are embedded in a duplicated segment of deoxyribonucleic acid (DNA) with homologous (X, Y, and Z boxes) and nonhomologous (I, II, and III) regions. The extent of specific mutations that delete a single α-globin gene are indicated by *salmon boxes,* and the limits of the breakpoints are indicated as *solid lines*. These deletions and the reciprocal chromosomes containing three functional α-globin genes result from misalignment and unequal recombination mediated by the homologous blocks. **B,** Unequal crossover through the Z box deletes 3.7 kb of DNA and produces the $-\alpha^{3.7}$ chromosome and its antitype, whereas recombination through the X box produces the $-\alpha^{4.2}$ chromosome and its antitype. The $-\alpha^{3.7}$ deletion can be further subdivided (I to III) by the exact location within the Z box where recombination occurs (see **A**). *(Modified from Higgs DR, Vickers MA, Wilkie AO, et al: A review of the molecular genetics of the human alpha-globin gene cluster.* Blood *73:1081–1104, 1989.)*

α_1 gene on a normal chromosome.[395] Persons homozygous for the leftward deletion ($-\alpha^{4.2}/-\alpha^{4.2}$), who carry two copies of the α_1 gene, express more α-globin than the anticipated 25% of normal.[410] Homozygotes for the $-\alpha^{3.7III}$ deletion ($-\alpha^{3.7III}/-\alpha^{3.7III}$), who carry two α_2 genes, express less than the anticipated 75% of normal.[410] The increased expression of the α_1 gene on the $-\alpha^{3.7}$ and $-\alpha^{4.2}$ chromosomes may be secondary to release of transcriptional interference from the upstream α_2 gene,[397] whereas the lower expression of the α_2 gene in the $-\alpha^{3.7III}$ deletion remains to be explained. An important consequence of this observation, however, is that common mutations that delete the α_2 gene ($\alpha^{3.7I}$ and $\alpha^{4.2}$) may lead to increased expression of the remaining α_1 gene and to a less severe clinical phenotype than predicted from expression studies of the native α-globin genes.[410] Single nucleotide substitutions that inactivate the α_2 gene do not affect α_1 expression and consequently lead to a more severe clinical phenotype than do single gene deletions.[2,15]

Triplicated α-gene chromosomes are observed in populations in which the $\alpha^{3.7I}$ and $\alpha^{4.2}$ chromosomes are present. The third gene is expressed and leads to a slight increase in the α-chain to β-chain ratio in homozygotes for the triplication, but this increase is generally of no clinical consequence.[411,412] However, if a triplicated α-gene chromosome is co-inherited with a β-thalassemia gene, thalassemia intermedia may be seen.[413,414] A unique deletion that removes the α_1 gene and some downstream sequence was recently described as a cause of α-thalassemia and appears to be due to a novel biologic mechanism.[415] As a result of the deletion, a promoter in the antisense orientation is brought into close proximity to the remaining α_2 gene. Antisense transcripts are created and appear to cause methylation of DNA and silencing of the chromatin in the region, thus attenuating transcription of the intact α_2 gene. Recent work in both yeast and human cells has begun to delineate the mechanisms that may be responsible for this phenomenon, which may normally play a role in physiologic gene regulation.[416]

Mutations That Remove Both α-Globin Genes

Illegitimate, nonhomologous recombination within the α-globin cluster results in partial or complete deletion of both α-globin genes and generates an α^0 chromosome.[2,388,417-421] (Note that the term α^+ and α^0 may refer to the expression of α-globin from a single gene or may refer to the presence or absence of an intact α-globin gene on a chromosome.) In some circumstances, the ζ-globin gene may also be encompassed by the deletion. The boundaries of many of the deletions that have been characterized are summarized in Figure 21-21. The geographic distribution of these lesions is more restricted than that of the α^+-thalassemia deletions, the most common being the $-^{SEA}$ (Southeast Asia) and $-^{MED}$ (Mediterranean) deletions, thus suggesting that they are rare genetic events. Theories concerning the mechanisms of these deletions are summarized elsewhere.[2]

Homozygotes for α^0 chromosomes (–/–) experience hydrops fetalis, whereas persons heterozygous for an α^+ chromosome and an α^0 chromosome ($-/-\alpha$ or $-/\alpha^T\alpha$) exhibit HbH disease. Increased expression of minute quantities of ζ-globin into adulthood may accompany some of the mutations in which the ζ gene is left intact by the deletion.[409] Sensitive radioimmunologic assays for the presence of ζ-globin chains in heterozygous adult carriers of these mutations have been devised,[422] and they may prove useful in areas such as Southeast Asia, where the incidence of the $-^{SEA}$ chromosome is as high as 3%.[423]

Mutations Not Linked to the Globin Gene Clusters That Alter Globin Gene Expression

X-Linked α-Thalassemia Associated with Mental Retardation Syndrome

Rare instances of α-thalassemia occurring in persons of Anglo-Saxon origin with phenotypically normal parents

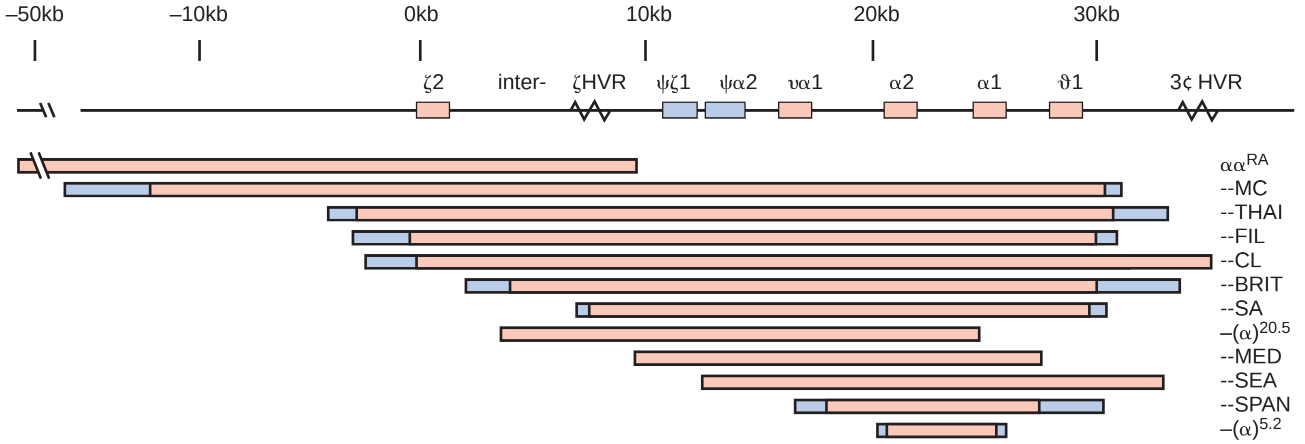

Figure 21-21 Deletion mutations that give rise to α^0-thalassemia. The organization of the α-globin cluster is shown. Expressed genes are represented by *salmon boxes*, whereas pseudogenes are shown as *blue boxes*. Two hypervariable regions (HVRs) are indicated as *zigzag lines*. Coordinates are in kilobase pairs (kb). The extent of each deletion is defined by a *salmon box* and the uncertainty of the breakpoints by *blue boxes*. The designation of the genotype is indicated to the right of each deletion. *(From Higgs DR, Vickers MA, Wilkie AO, et al: A review of the molecular genetics of the human alpha-globin gene cluster.* Blood *73:1081–1104, 1989.)*

first drew attention to a new syndrome.[424] Further investigation revealed the commonly seen association of profound mental retardation, facial anomalies, and genital abnormalities.[79] Important recent studies demonstrated mutation of the *ATRX* gene, a member of the DNA helicase superfamily and presumed global transcriptional regulator, as the underlying basis of this syndrome.[80] The exact function of this gene in globin gene regulation is not exactly clear, although recent studies suggest that it may be involved in binding to tandem repeats and regulating allele-specific expression of genes such as the α-globins.[425]

Acquired Hemoglobin H Disease

A particularly severe, acquired form of HbH disease has been described in elderly men with clonal myeloproliferative disorders.[426-429] In this setting, levels of HbH approaching 60% may be seen.[402] Extremely low α-chain to β-chain synthesis ratios and low α-globin mRNA levels have been documented in bone marrow cells from affected individuals.[427,428] Residual α-globin mRNA expression may be derived from nonclonal erythroid cells. A bimorphic population of cells is present on examination of the peripheral blood smear. The manifestations of hemolytic disease caused by HbH may increase and decrease with the clinical course of the myeloproliferative disorder.[427] This condition has been shown to be due to acquired mutations in the *ATRX* gene, which is also mutated in the syndrome of X-linked α-thalassemia associated with mental retardation.[430] Interestingly, similar mutations that are somatically acquired in this acquired condition confer a much more severe α-thalassemia phenotype in comparison with those acquired in the germline in the syndrome of X-linked α-thalassemia associated with mental retardation.[431]

Silent β-Thalassemia

Hematologically normal “silent carriers” of β-thalassemia are identified through family studies.[1,6,432-435] Some instances of “silent” β-thalassemia may be attributed to mutations that cause a very modest reduction in β-globin gene expression—the −101 promoter mutation[146,259] and the +1 cap site mutation[158]—or attributed to the inheritance of triplicated α-globin gene chromosomes.[413,414] In an Albanian family in which the father was a silent carrier, the mother had high-HbA_2 β-thalassemia trait, and two children had β-thalassemia, the silent carrier determinant did not appear to segregate with either of the paternal β-globin gene clusters.[436] Subsequently, a number of reports of families in which a β-thalassemia mutation appeared to be unlinked to the β-globin complex have been reported.[437-439] These rare instances of unlinked β-thalassemia may be due to mutations in *trans*-acting factors. However, all these patients did not have the syndromic features seen in persons with the previously characterized *trans*-acting regulatory factor mutations (see the section on β-thalassemia mutants unlinked to the β-globin complex). Thus new insight may be gained from genetic analysis of these rare cases. However, caution must be applied in the analysis of such cases, because at least some of these cases may be due to an increase in the number of α-globin genes present on a single α-globin locus of these patients.[440,441]

Hereditary Persistence of Fetal Hemoglobin Unlinked to the β-Globin Locus

Ordinarily, HbF constitutes less than 1% of the total hemoglobin in normal adult erythrocytes and is restricted to a subpopulation of erythrocytes (F cells) that represent between 3% and 7% of the total number of red blood cells.[7,8] Both the percentage of F cells present in the circulation and the amount of HbF are under genetic control, and evidence suggests that the determinants are not linked to the β-globin gene cluster.[442]

Although these genetic determinants were initially thought to be traits that could be inherited in a Mendelian fashion, linkage studies failed to identify such genes. More recent GWAS has uncovered a number of common genetic variants that lead to natural variation in the level of HbF. Although some common variants are linked to the β-globin gene cluster itself, others are unlinked to this region, as discussed previously in this chapter. Rare determinants in specific families that alter HbF levels may still exist, and further work with modern sequencing approaches may help to elucidate the genetic basis for such observations.

CLINICAL HETEROGENEITY OF THALASSEMIA SECONDARY TO DIVERSITY OF MUTATIONS

In the previous sections, the extraordinary array of mutations associated with the clinical syndrome of thalassemia has been described. In populations in which thalassemia is prevalent, different types of mutations that affect genes of either the α-globin, β-globin, or both globin clusters may coexist. Frequently, patients are compound heterozygotes for these mutations. The relative degree to which globin chain synthesis is impaired reflects this genetic heterogeneity and determines the clinical phenotype. In the following clinical description of the thalassemia syndromes, we emphasize such genetic interrelationships.

α-Thalassemia

Nomenclature and Genetics of α-Thalassemia

α-Thalassemia is divided into four clinical subsets that reflect the extent of impairment in α-globin chain production: silent carrier (–α/αα), α-thalassemia trait (–α/–α or –/αα), HbH disease (–/–α), and hydrops fetalis (–/–; see Table 21-6). Before the introduction of molecular analysis, these syndromes were classified on the basis of red blood cell parameters (hemoglobin level, mean corpuscular volume [MCV], mean corpuscular hemoglobin [MCH], globin biosynthetic ratio, presence of inclusions, and HbH [β_4] levels), as well as the manner in which they interacted genetically to produce different phenotypes. Much of this early work relied on the study of Asian populations in which α-thalassemia is particularly common.[1]

The silent carrier state for α-thalassemia, in which a single α-globin gene on a chromosome is inactivated, has traditionally been designated α-thalassemia-2. Homozygosity for α-thalassemia-2 or heterozygosity for an allele causing more severe disease in which both α-globin genes are inactivated leads to α-thalassemia trait, also termed α-thalassemia-1. According to the historical nomenclature, HbH disease reflects heterozygosity for α-thalassemia-2 and α-thalassemia-1, whereas hydrops fetalis results from homozygosity for α-thalassemia-1.

Advances in molecular characterization of the α-globin gene cluster have clarified the genetic basis of these phenotypes. Weatherall and colleagues proposed a more informative nomenclature for these mutations.[1,2] Each chromosome may be designated as α^+ or α^0 to indicate the presence or absence of any α-globin chain production derived from that chromosome. This designation is referred to as a haplotype and should be distinguished from use of the term haplotype in describing the linkage of DNA polymorphisms on a chromosome. Haplotypes are further subdivided by the status of each α-globin gene on a chromosome. As discussed previously, mutations may be of the deletion or nondeletion type. Normal persons are designated (αα/αα) to indicate the presence of four active α genes, two on each chromosome 16, with the first position corresponding to the α_2 gene and the second position to the α_1 gene. Deletion of a single α-globin gene on a chromosome is designated (–α/), whereas deletion of both genes is indicated as (–/). Further refinement of this nomenclature includes a designation of the specific mutation; for example, $(-^{SEA}/)$ signifies the α^0 deletion mutation that is common in Southeastern Asian populations (see Fig. 21-21), and $(-\alpha^{3.7}/)$ symbolizes the α^+ rightward α-gene deletion that is extremely common in the American black population (see Fig. 21-21). Nondeletion mutations in a haplotype are designated in this scheme by a superscript T ($\alpha\alpha^T$) and can be more precisely described by symbols for the specific mutation and the gene affected. For example, ($\alpha^{CS}\alpha$) designates a chromosome bearing the CS chain termination mutation affecting the α_2 gene (see Table 21-2), and ($\alpha^{QS}\alpha$) designates a chromosome bearing the α gene with a substitution in codon 125 that leads to the synthesis of an unstable globin (see Table 21-2). This shorthand nomenclature is extremely useful when a patient's genotype is known in detail and has simplified description of the many genotypes that interact to generate the heterogeneous clinical syndromes.

At least 30 mutations that may inactivate one or both α-globin genes are known; thus the different combinations of chromosomes bearing α-thalassemia mutations number more than 200. The number of occurrences of the different genotypes and haplotypes define the spectrum of disease observed in a given ethnic group. For example, severe forms of α-thalassemia (HbH disease and hydrops fetalis) are uncommon in blacks. In this group the single-deletion chromosome is very common,[443,444] whereas chromosomes with two defective α genes are quite rare. In some circumstances the phenotype of HbH disease is not readily related to genotype. Indeed, there is a significant spectrum of disease severity in persons from the Southeast Asian area with the same genotype $(-\alpha^{3.7}/-^{SEA})$.[408] The observed phenotype may be further complicated by the inheritance of another hemoglobin disorder (β-thalassemia) or the influence of environmental factors such as iron or other nutritional deficiency.

Silent Carrier

The silent carrier state, or the α-thalassemia-2 defect, is due to the presence of a mutation affecting only one α-globin gene. Most often this defect occurs because of a deletion mutation (–α/αα). Patients who are silent carriers for α-thalassemia have three rather than four functional α-globin genes.[400,445] Thus the impairment in α-globin synthesis is very mild. Significant overlap of their globin biosynthetic ratio occurs with both that of normal subjects and that of persons with only two functional α-globin genes (Fig. 21-22). Similarly, the mean MCV of patients with three functional genes is slightly lower than that in normal subjects, but significant overlap between the two groups exists.[2] Despite these differences

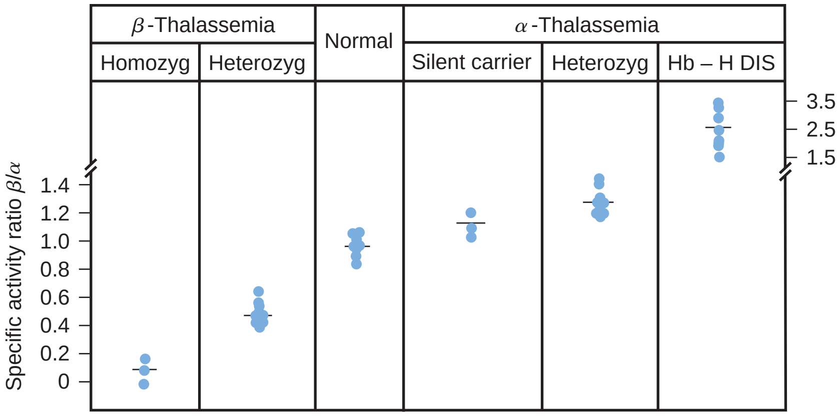

Figure 21-22 Biosynthetic α-globin to β-globin ratio in various forms of thalassemia. Peripheral blood cells were incubated with [^{14}C]leucine for 2 hours in autologous plasma. The globin chains were isolated by ion exchange chromatography. The specific activity of the chains and the ratio of their radioactivities were then calculated. *Hb,* Hemoglobin. *(Modified from Nathan DG. Thalassemia.* N Engl J Med *286:586–594, 1972.)*

that become apparent upon comparison of groups with different numbers of α-globin genes, there is no reliable way to diagnose silent carriers of α-thalassemia by hematologic criteria. Diagnosis has been reported by detection of small amounts of hemoglobin Bart's in cord blood,[1] but additional studies indicate that this approach is unreliable in ascertaining the presence of the silent carrier state.[446,447] However, a more recent study in the United Kingdom using high-performance liquid chromatography (HPLC) and genotyping to verify α-globin genotype on fresh cord blood samples demonstrated that HPLC is a reliable technique for determining the silent carrier state.

Silent Carrier Variant: Hemoglobin CS. Some silent carriers of α-thalassemia produce small quantities of slowly migrating hemoglobins (Fig. 21-23) that contain elongated α-globin chain variants resulting from termination codon mutations (see Table 21-2 and Fig. 21-14).[220-224] The original elongated α-chain variant, hemoglobin Constant Spring, was named for the small Jamaican town that was the residence of the Chinese family in whom these hemoglobins were first discovered.[221] The family had three children with HbH disease; each had a small amount of the abnormal hemoglobins. One parent had typical thalassemia trait, whereas the other had normal red blood cells but, in addition, had approximately 1% of the abnormal hemoglobin. Similar slowly migrating hemoglobins have been found in other racial groups in Thailand and Greece.[448] Persons homozygous for the α^{CS} mutation ($\alpha^{CS}\alpha/\alpha^{CS}\alpha$) have a clinical syndrome similar to HbH disease, although their erythrocytes contain hemoglobin Bart's (γ_4) rather than HbH and the degree of anemia and the extent of abnormalities in red blood cell indices are milder than those in most patients with HbH disease.[449] Compound heterozygotes for the α^0 and α^{CS} haplotypes ($-/\alpha^{CS}\alpha$) exhibit typical HbH disease.

α-Thalassemia Trait

Two genotypes (–/αα and –α/–α) that reflect inactivation of two α-globin genes are associated with α-thalassemia trait. Substitution mutations that affect the predominant α_2 gene ($\alpha^T\alpha/\alpha\alpha$) may also lead to α-thalassemia trait. The extent of the observed changes in red blood cell indices mirrors the reduction in α-globin production seen with each genotype, with the (–α/–α) genotype being less affected than the (–/αα) genotype. α-Thalassemia trait is characterized by marked microcytosis and hypochromia of red blood cells in conjunction with mild anemia and erythrocytosis (see Table 21-6). Levels of HbA_2 and HbF are generally normal or low. Diagnosis of this condition is typically made by family studies or by exclusion of iron deficiency and β-thalassemia trait. The incidence is particularly high in Asian populations and less in African, Mediterranean, and American black populations. Even in the neonatal period, the red blood cells appear hypochromic and microcytic. The proportion of hemoglobin Bart's may be as high as 1% in the blood of normal newborns, but levels of 4% to 6% are attained in infants who are

later shown to have α-thalassemia trait[1] (see Table 21-6). Beyond the neonatal period, biochemical markers such as HbA_2 and HbF in β-thalassemia are not particularly helpful in confirming the diagnosis of α-thalassemia trait. The one exception occurs in circumstances in which the expression of ζ-globin is increased because of deletion of both α-globin genes on a chromosome.[409,421,450] In Southeast Asia, where the $-^{SEA}$ allele is common, a sensitive radioimmunoassay allows detection of ζ-globin chains in adult carriers of this mutation.

Measurement of the β-to-α biosynthetic ratio has little place in the routine diagnosis of α-thalassemia trait. Although detection of impaired α-globin synthesis has been reported,[451,452] measurement is technically difficult because these persons have a low reticulocyte count and the measured values overlap with those found in healthy persons (see Table 21-6). Iron deficiency may raise the measured β-toα biosynthetic ratio, thus further complicating interpretation.[453-456] Consequently, in most patients the diagnosis of α-thalassemia trait is established by red blood cell structure and parameters, coupled with exclusion of β-thalassemia trait and iron deficiency. Gene deletions responsible for deficient α-globin production can be demonstrated by restriction endonuclease mapping; this technique may be applied when an accurate diagnosis is critical. Newer technology allows polymerase chain reaction detection of deletion[457] and triplication[458] of α genes, and it has the same level accuracy as the more cumbersome Southern blotting and DNA hybridization with a ϕζ-globin gene probe.

Hemoglobin H Disease

Genetics. HbH disease occurs in persons who have only a single fully functional α-globin gene. The genotypes leading to HbH disease are diverse.[2] Most common is heterozygosity for the single- and double-deletion chromosomes (–/–α). As a result, HbH disease is observed most often in Southeast Asia ($-^{SEA}/-\alpha^{3.7}$) and the Mediterranean basin ($-^{MED}/-\alpha^{3.7}$), where the incidence of both the α^+ and α^0 haplotypes is significant. Nondeletion mutations may also interact to cause HbH disease. As discussed earlier, the α_2 genes are responsible for the production of approximately 75% of the total α-globin chains. Mutations that decrease expression from the α_2 gene ($\alpha^T\alpha/$) result in an α+ haplotype that produces fewer α-globin chains than a deletion α+ haplotype (–α/) does. Thus homozygosity for mutations in both α_2 genes ($\alpha^T\alpha/\alpha^T\alpha$) is phenotypically equivalent to deletion of three genes and is associated with HbH disease and not α-thalassemia trait.[2,15] Consistent with this observation, nondeletion α+-thalassemia haplotypes that are paired with α^0-thalassemia haplotypes ($-/\alpha^T\alpha$) lead to more severe HbH disease than does the interaction of the deletion α+ haplotypes (–/–α).

Hemoglobin Pattern. Anemia of moderate severity characterized by hypochromia, microcytosis, striking red blood cell fragmentation (Fig. 21-24), and the presence of a fast migrating hemoglobin, HbH (β_4), on electrophoresis (see Fig. 21-23) may be shown to represent an α-thalassemia syndrome by measurement of the β-to-α biosynthetic ratio.[451,459,460] Incubation of peripheral blood reticulocytes with [^{3}H]leucine and subsequent chromatographic resolution of the globins indicate that such patients have a twofold to fivefold excess of β-chain synthesis (see Table 21-6 and Fig. 21-22). These excess β chains form HbH, which accounts for 5% to 30% of the total hemoglobin in patients with HbH disease.[461] In approximately 50% of persons with HbH disease in Southeast Asia, small quantities of hemoglobin CS are found (see Fig. 21-23). HbH disease may be suspected in anemic neonates in whom all the red blood cells are severely hypochromic. At birth, patients with HbH disease also have large amounts of hemoglobin Bart's (γ_4). In patients with HbH disease and an intact spleen, incubation of peripheral blood cells in brilliant cresyl blue produces many small inclusions in most red blood cells (Fig. 21-25). The dye induces precipitation of HbH by a redox reaction. In contrast, large and usually single preformed inclusions (Heinz bodies) may be visualized with methyl violet in the red blood cells of patients who have undergone a splenectomy (see Fig. 21-25).[110,462] These inclusions are composed of precipitated β-globin rendered insoluble by hemichrome formation or by interaction of β-globin sulfhydryl groups with the red blood cell membrane.[110,463]

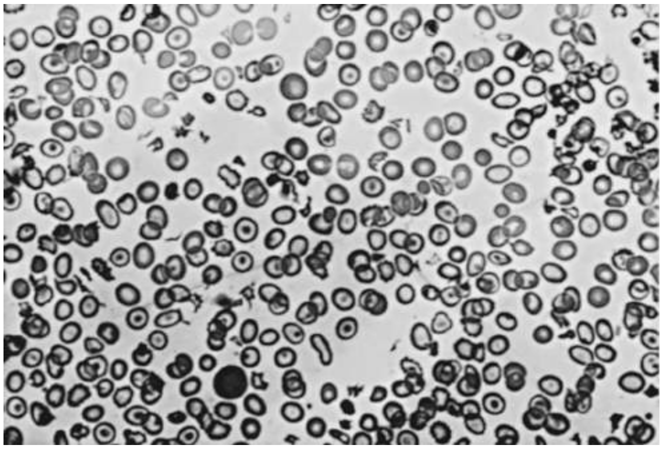

Figure 21-24 Peripheral blood smear from a patient with hemoglobin H disease.

Pathophysiology. HbH exhibits no Bohr effect or heme-heme interaction and thus is not effective for oxygen transport under physiologic conditions.[464] Consequently, patients with appreciable amounts of HbH have a more severe deficit in functional hemoglobin and oxygen-carrying capacity than the measured hemoglobin concentration might suggest. Red blood cells containing HbH are sensitive to oxidative stress, thus accounting for the enhanced red blood cell destruction that may occur with the administration of oxidant drugs such as sulfonamides.[465] As erythrocytes age and lose their capacity to withstand oxidant stress, precipitation of HbH occurs and leads to premature destruction of circulating red blood cells[110]; hence HbH is primarily a hemolytic disorder.[462,466] Inclusions of HbH are rarely seen in bone marrow cells,[467] and erythropoiesis is fairly effective.[466]

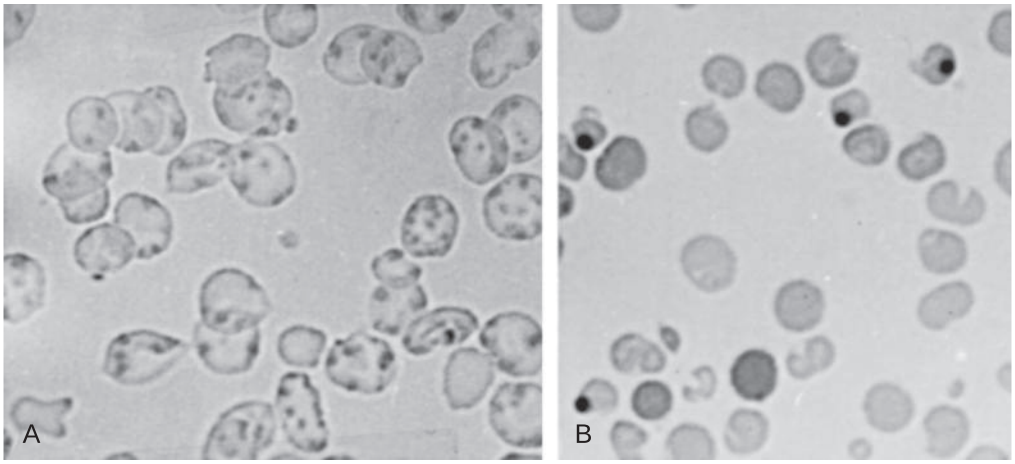

Figure 21-25 Red blood cell inclusions in hemoglobin H disease. **A**, Inclusions induced by incubation of peripheral blood in 1% brilliant cresyl blue and 0.4% citrate for 30 minutes at 37°C (the patient had not undergone a splenectomy). **B**, Preformed inclusions in the peripheral blood of a patient who had undergone a splenectomy stained by a new methylene blue reticulocyte stain.

Clinical Features. Typical patients with HbH disease live quite normally. Generally, the anemia is moderate with a hemoglobin concentration of 7 to 10 g/dL, although occasional patients may have hemoglobin levels as low as 3 to 4 g/dL.[1] The complications of HbH disease are related to chronic hemolysis. Jaundice and hepatosplenomegaly are commonly present. Folic acid deficiency, pigment gallstones, leg ulcers, and increased susceptibility to infection are also observed. Hemolytic episodes may be precipitated by drugs or infection. Iron overload is uncommon but may occur in patients receiving transfusions and those older than 45 years.[468] Development of the characteristic thalassemic facies, which reflects expansion of marrow space equivalent to that seen in patients with severe β-thalassemia, is rare. Usually only moderate bone marrow erythroid hyperplasia is evident.[456]

Therapy. Consistent with the benign course of HbH disease, treatment is primarily supportive. Therapy includes supplementation with folic acid, avoidance of oxidant drugs and iron salts, prompt treatment of infectious episodes, and judicious use of transfusions. Splenectomy should be contemplated in patients with HbH disease only if hypersplenism is present as reflected by leukopenia, thrombocytopenia, and worsening anemia or the development of a transfusion requirement in a patient whose condition was previously stable. Thrombocytosis after splenectomy may be complicated by a clotting diathesis, recurrent pulmonary emboli, and pulmonary hypertension, particularly in patients with severe HbH disease and a fairly normal hematocrit.[468-470] The use of measurements of red blood cell survival and splenic sequestration by chromium-51 labeling of red blood cells is controversial in making a clinical decision regarding splenectomy because the label binds selectively to β-globin chains and may, by virtue of selective removal of HbH inclusions from red blood cells in the spleen, give a falsely high index of splenic destruction.[471] Other studies, however, suggest that results from the ^{51}Cr technique may be valid.[472]

Other Hemoglobin H Syndromes

Syndrome of α-Thalassemia with Mental Retardation. Patients with a syndrome characterized by mental retardation and a form of α-thalassemia that cannot be explained by simple Mendelian inheritance of an α-thalassemia gene have been described.[424,473] In rare patients, the mutation arises as a de novo event in a paternal germ cell. These patients can be divided into two distinct syndromes (deletion and nondeletion) on the basis of their clinical features and the results of molecular analysis of their α-globin gene clusters.

Patients have been described with extensive deletions involving chromosome band 16p3.3 or, alternatively, with deletions resulting from unbalanced chromosome translocations that also lead to aneuploidy in a second chromosome. Patients with deletion mutations exhibit mild to moderate mental retardation and a broad spectrum of dysmorphic features. Other rare patients are characterized by more severe mental retardation and a uniform pattern of dysmorphic features, including genital abnormalities, but no detectable deletions involving the α-globin gene cluster.[79] Such patients fall into the category of the syndrome of X-linked α-thalassemia with mental retardation. As noted earlier, the affected gene is a putative global regulator (*ATRX*).[80]

Although these disorders are seen rarely, they may be underrecognized. This underrecognition is particularly true of ethnic groups in which α-thalassemia is uncommon, and the mild hematologic findings in patients who do not inherit a second α-thalassemia gene might be overlooked. Infants with uncharacterized mental retardation should be studied with techniques suitable for detection of a deficiency in α-globin synthesis.

Acquired Hemoglobin H Disease. HbH is also found rarely in the red blood cells of patients with erythroleukemia or a myeloproliferative syndrome.[426-428] The disorder may be clonal and displays a striking male predisposition (85% of confirmed instances).[424] The clinical features manifested by these patients are those of their primary disorder; the finding of HbH is incidental to the outcome of the disease, although striking red blood cell abnormalities and active hemolysis may be present. The genetic mechanism of this syndrome appears to involve abnormal regulation of α-gene expression because of a mutation affecting the *ATRX* genetic locus (discussed earlier).

Hydrops Fetalis

Genetics. Homozygosity for the α^0 haplotype (–/–) leads to hydrops fetalis, a disorder that is particularly common in Southeast Asia where the α^0 haplotype is seen frequently. In rare infants from Greece and Southeast Asia, hydrops fetalis has been shown to result from the interaction of α^0 haplotypes with nondeletion α^+ haplotypes.[474-476]

Hemoglobin Pattern. The birth of stillborn infants to parents with α-thalassemia trait reflects the most severe form of α-thalassemia.[477,478] Because of the inability to synthesize any α-globin, their blood contains only hemoglobin Bart's (γ_4), HbH (β_4), and small amounts of Hb Portland ($\zeta_2\gamma_2$) within red blood cells displaying morphologic changes characteristic of severe thalassemia.[479,480]

Pathophysiology. Although the hemoglobin concentration averages 6.2 g/dL, both HbH and hemoglobin Bart's have high oxygen affinity and no subunit cooperativity, and therefore a hydropic infant has very little functional hemoglobin. Viability in utero is maintained by the presence of small quantities of hemoglobin Portland 1 and 2.

Clinical Features. Generally, affected infants are delivered stillborn at 30 to 40 weeks' gestation or die shortly after delivery at term.[423,479] Infants are grossly edematous or hydropic as a result of congestive heart failure induced by severe anemia. The blood smear is characterized by large hypochromic macrocytes and numerous nucleated red blood cells. At autopsy, extensive extramedullary hematopoiesis and placental hypertrophy are seen. A high incidence of toxemia of pregnancy and postpartum hemorrhage is observed in mothers of hydropic infants,[456,481] presumably as a consequence of the massive placenta. Hence early recognition of the disorder in at-risk pregnancies by prenatal diagnosis should lead to consideration of termination of the pregnancy.

Therapy. At least five infants born prematurely with hydrops fetalis have survived with the use of chronic transfusion regimens.[482,483] Intrauterine transfusion of fetuses with hydrops fetalis should also be considered if treatment after delivery is contemplated.[484] Marrow transplantation may be considered if the affected infant is delivered safely.

Mild β-Thalassemia

Silent Carrier

A silent carrier state for β-thalassemia was recognized through the study of families in which affected children had a more severe β-thalassemia syndrome than a parent with typical β-thalassemia trait.[1,6,432,435] A study of the "normal" parent often revealed mild microcytosis or a slight impairment in β-globin synthesis on radiolabeling of the globin chains in peripheral blood reticulocytes. Characteristically, silent carriers of β-thalassemia have normal levels of HbA_2. These silent carriers must be distinguished from persons whose red blood cells have all the stigmata of β-thalassemia trait but have normal levels of HbA_2. Several patients who are homozygous for the silent carrier β-thalassemia gene have been described.[1] Anemia is moderate (a hemoglobin concentration of 6 to 7.0 g/dL), and these patients rarely require transfusion. Hepatosplenomegaly may be significant. HbF values range from 10% to 15%, and the HbA_2 level is elevated to the range normally seen in persons with thalassemia trait.

The silent carrier state of β-thalassemia appears to be a distinct clinical and biochemical entity. The underlying molecular defects cause only a modest reduction in β-globin synthesis. Two point mutations in the β-globin gene region have been linked to the silent carrier phenotype. The −101 promoter mutation appears to be a common cause of silent β-thalassemia in the Italian population[150] and has been observed in Bulgarian and Turkish persons,[146] whereas the +1 cap site Inr mutation is associated with a silent carrier phenotype in an Indian family.[158] As noted earlier, rare instances of silent β-thalassemia secondary to mutations unlinked to the β-gene cluster have been reported.

β-Thalassemia Trait

Genetics. In 1925, Rietti[485] described Italian patients with mild anemia whose red blood cells exhibited increased resistance to osmotic lysis. A similar syndrome was later recognized in American patients of Italian descent by Wintrobe and colleagues,[486] who noted that both parents of a patient with Cooley anemia also had this syndrome. Detailed analysis of several pedigrees by Valentine and Neel[487] and others[488,489] established the fact that this form of thalassemia occurs in persons who are heterozygous for a mutation that affects β-globin synthesis. Expression of one β gene is impaired by mutation, whereas the other gene is normal.

Hemoglobin Pattern. Characteristically, HbA_2, HbF, or both are elevated in patients with β-thalassemia trait, although normal levels are observed occasionally. The relative amounts of HbA_2 or HbF have been used to classify thalassemia trait, which has relevance to the molecular lesion in certain instances and also to the severity of the disease in homozygous offspring.

Globin Biosynthetic Ratio. In peripheral blood reticulocytes, the measured β-to-α biosynthetic ratio varies from 0.5 to 0.7, as predicted for inactivation of a single β gene (see Fig. 21-22). However, when bone marrow cells are incubated with [^{3}H]leucine, the measured β-to-α biosynthetic ratio is often 1:1 in patients with heterozygous β-thalassemia.[490-494] The capacity of bone marrow cells to degrade free α-globin by proteolysis may explain why it is difficult to demonstrate unbalanced synthesis of β- and α-globin chains in the marrow cells of heterozygotes. The measured β-to-α ratio is approximately 0.5 in pulses of 10 to 20 minutes, but if the incubation of bone marrow cells is prolonged, proteolysis apparently destroys the excess newly synthesized α-globin.[495,496] Fractionation of bone marrow cells after incubation in [^{3}H]leucine demonstrated that proteolysis is most efficient in the earliest erythroid cells, namely, proerythroblasts and basophilic erythroblasts.[496] The impairment in β-globin synthesis becomes easier to detect as erythroid cells mature, thus accounting for the reduced β-to-α biosynthetic ratio that is usually found in peripheral blood reticulocytes.

δ-Globin Synthesis. Among inherited anemias, the elevation in HbA_2 level is unique to β-thalassemia. The absolute quantity of HbA_2 present in red blood cells is a complex function of the inherent capacity for δ-globin chain synthesis and factors regulating rates of hemoglobin dimer and tetramer assembly. As discussed earlier, δ-globin is normally expressed at a low level, approximately 2.5% that of β-globin. The level may be reduced further by mutations that affect δ-globin expression. Heterozygous[497,498] and homozygous[499] states have been described. δ-Thalassemias reflect point mutations that completely silence the already defective δ-globin genes.[287,288,306,435,500-502]

In heterozygous β-thalassemia, the observed increase in HbA_2 represents a relative as well as an absolute increase in the quantity of HbA_2 per red blood cell from the normal level of 0.6 to 0.7 pg to 1.0 pg.[1] The increased amount of HbA_2 contains δ-globin chains derived from the δ gene adjacent to the mutant β gene, as well as from the δ gene on the opposite chromosome, which has been inferred from the study of β-thalassemia heterozygotes, who also have a variant δ chain.[503] The increase in the HbA_2 level can be accounted for by enhanced incorporation of δ-globin chains into hemoglobin dimers as a consequence of deficient β-globin chain production (see the earlier discussion on hemoglobin assembly).[230]

Environmental factors also influence the absolute level of HbA_2. Iron deficiency leads to a decrease in the level of HbA_2, which may become normal in thalassemia heterozygotes and therefore mask the diagnosis of β-thalassemia trait. In such instances, the level of HbA_2 becomes elevated with iron repletion.[504] An increase in the level of HbA_2 may be seen in acquired megaloblastic disorders associated with either folic acid or vitamin B_{12} deficiency.[504]

Clinical Features. Peripheral blood smears from patients with β-thalassemia trait are shown in Figure 21-26. Microcytosis, hypochromia, targeting, basophilic stippling, and elliptocytosis may be striking features, although the red blood cells may be nearly normal in occasional patients. The bone marrow is characterized by mild to moderate erythroid hyperplasia; red blood cell survival is modestly decreased, and slight ineffective erythropoiesis is present.[505] Inclusions in bone marrow cells and peripheral red blood cells are rare. Similar hematologic parameters appear to characterize Thai, Chinese, Greek, British, and Italian populations with β-thalassemia trait,[506-509] whereas African Americans appear to have a milder syndrome.[510] Hepatomegaly and splenomegaly have been reported in 10% to 19% of Italian and Greek patients but are less common in other groups.[508,509] Iron or folic acid deficiency, pregnancy, or intercurrent illness may exacerbate the anemia in patients with thalassemia trait.

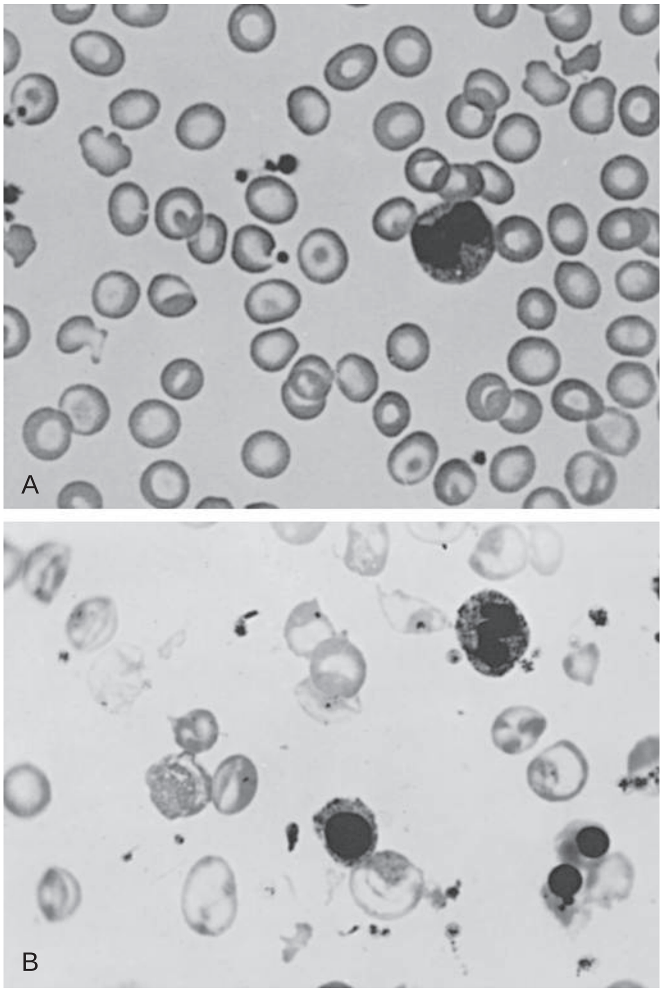

Figure 21-26 Peripheral blood smears from patients with heterozygous β-thalassemia (**A**) and homozygous β-thalassemia (**B**) after a splenectomy.

Therapy. No therapy is required for thalassemia trait, but genetic counseling is imperative. The homozygous offspring of two persons with high-HbA_2 β-thalassemia trait usually have transfusion-dependent anemia and thalassemia major, but they may sometimes have a thalassemia intermedia phenotype. The precise nature of the mutation or mutations in homozygous persons is one factor in determining the clinical phenotype.

β-Thalassemia Trait Phenotypes

High-A_2 β-Thalassemia. High-A_2 β-thalassemia is the most common form of β-thalassemia trait. HbA_2 levels vary from 3.5% to 8.0%, whereas the HbF level varies from less than 1% to 5%.[1,506-510] The vast majority of single-base mutations resulting in β-thalassemia (see Table 21-2) lead to typical high-HbA_2 β-thalassemia trait. Although individual mutations variably reduce β-globin synthesis, efforts to differentiate the effect of specific mutations in heterozygous persons have largely been unrewarding.[1,508,511,512] In blacks, β^0 and β^+ mutations can often be distinguished in individual families by the rate of occurrence of double heterozygotes for a β-thalassemia mutation and the β^S mutation. In this population, MCV and MCH values are higher in β^+ heterozygotes than in β^0 heterozygotes, but circulating hemoglobin concentrations are nearly equivalent.[510,513] The common mutations found in American blacks, most notably residing in the ATA box of the promoter (see Table 21-2), only modestly impair β-globin gene expression,[46,172] which perhaps accounts for the relatively mild phenotype of many persons with heterozygous or homozygous β^+-thalassemia in this population.

δβ-Thalassemia. Persons heterozygous for δβ–thalassemia have increased levels of HbF (5% to 15%) and low HbA_2 levels. This phenotype is most often generated by deletions that remove most or all of the coding sequences of the δ- and β-globin genes (see Table 21-4). The propensity of these deletion mutations for enhancement of the expression of γ-globin genes contributes to a relatively mild phenotype in homozygous persons or those in whom a δβ-thalassemia deletion is inherited along with a thalassemia allele with a typical substitution mutation.

High-A_2, High-F β-Thalassemia. A distinct variant of β-thalassemia trait has been described in which the level of HbA_2 is elevated and the level of HbF is also elevated (5% to 20%).[514-516] This form of thalassemia trait is associated with deletions of the β-globin gene that leave the δ and γ genes intact (see Table 21-4).

Normal-A_2 β-Thalassemia. This form of β-thalassemia trait should be distinguished from the silent carrier state. Although both are characterized by low or normal HbA_2 levels, the red blood cells in persons with normal-HbA_2 β-thalassemia are characteristically hypochromic and microcytic,[434,517] in contrast to silent carriers, whose red blood cells appear near normal.[424,433] Persons who co-inherit this type of β-thalassemia allele from one parent along with a high-HbA_2 β-thalassemia allele from the other usually have severe transfusion-dependent β-thalassemia.

This phenotype is thought to represent co-inheritance of mutations (usually deletions) that decrease β- and δ-gene function. The mutations in the δ-globin gene may be present on the same chromosome or on the opposite chromosome from the β-thalassemia gene.[287,288,306,435,500-502]

Differential Diagnosis of Thalassemia Trait. In clinical practice, thalassemia trait must be distinguished from iron deficiency (see Chapter 11 for additional discussion of the differential diagnosis of microcytosis and iron deficiency). Frequently the differential diagnosis may be suspected from red blood cell indices; mild erythrocytosis and marked microcytosis are characteristic of thalassemia trait (Table 21-7).[518-520] The red blood cell count is usually decreased in patients with iron deficiency, whereas red blood cell volume may be normal or decreased, depending on whether the iron deficiency anemia is acute or chronic,[521-524] but red blood cell volume is rarely as low as in persons with thalassemia trait. The mean corpuscular hemoglobin concentration (MCHC) is usually normal in persons with thalassemia trait, whereas the MCHC may be low in a subset of cells in persons with iron deficiency; in both syndromes the hypochromic appearance of the red blood cells reflects their small size, diminished hemoglobin content, and high surface-to-volume ratio. The red blood cell distribution width, a parameter available in modern automated cell counters, was originally believed to distinguish between iron deficiency and other causes of microcytosis.[525,526] However, the red blood cell distribution width is also increased in the thalassemias and other hemoglobinopathies and is not a useful independent discriminator.[527-531] The absence of stainable iron

TABLE 21-7 Hematologic Parameters in Thalassemia Trait and Iron Deficiency

Parameter	α-Thal	β-Thal	Iron Deficiency
Hemoglobin concentration (g/dL)	12.6 ± 1.1	M—12.6 ± 1.4 (697)*	10.2 ± 1.6 (715)

in a bone marrow specimen is highly suggestive of iron deficiency, but the presence of iron does not necessarily exclude an iron-responsive anemia.

Several formulas have been developed to assist in the diagnosis of thalassemia trait during the assessment of microcytic hypochromic anemia (Table 21-8).[522,532,533] None of the discriminant functions is infallible. Nonetheless, the Mentzer index[522] is useful as an office screening test. More accuracy in separating thalassemia trait from iron deficiency may be achieved with the England and Fraser function,[533-535] but when both conditions exist simultaneously, all indices are subject to error. Additional discriminant functions and automated protocols have been proposed that may also prove useful.[536-538] Free erythrocyte protoporphyrin, which is often incorporated into the initial workup of hypochromic microcytic anemia in childhood to screen for lead exposure, is an additional useful test for patients suspected of having thalassemia trait.[539,540] This technique has been especially helpful in evaluating newly arrived Southeast Asian refugees to the United States.[541] Of course, measurement of transferrin saturation or ferritin may also be used to verify or exclude the diagnosis of iron deficiency. The ratio between microcytic (MCV <61 fL) and hypochromic (MCHC <28 g/dL) erythrocytes is a helpful parameter. A ratio greater than 1.0 is highly suggestive of thalassemic trait, whereas a ratio less than 1.0 is mostly associated with iron deficiency.

In office practice the distinction between thalassemia trait and iron deficiency generally depends on examination of peripheral blood smears and, above all, the patient's clinical history, as well as measurement of red blood cell indices in the parents. It is worth remembering that patients with thalassemia trait are not immune to iron deficiency. In these patients, iron deficiency may mask increases in the levels of HbA_2 and HbF that would otherwise suggest a diagnosis of β-thalassemia.

After iron deficiency is excluded, differential diagnosis between α- and β-thalassemia trait depends on measurement of HbA_2 and HbF levels (see Table 21-7) and rarely if ever on measurement of the α-to-β biosynthetic ratio in peripheral blood reticulocytes. In patients with microcytosis, hypochromia, and erythrocytosis but without evidence of iron deficiency or altered HbA_2 and HbF levels, α-thalassemia is the most probable diagnosis. When both α- and β-thalassemia coexist, changes in the levels of HbF and HbA_2 characteristic of β-thalassemia trait may not be present[116] (discussed later). Molecular genetic analysis and family studies are often necessary to define these complex interactions.

Severe β-Thalassemia

Historical Perspective

It was not until Thomas Cooley, a Detroit pediatrician, first described the clinical entity that was to bear his name that thalassemia major was recognized as a distinct disease.[542,543] Cooley recognized similarities in the appearance and clinical course of four children of Greek and Italian ancestry. These children exhibited severe anemia (hemoglobin concentration of 3 to 7 g/dL), massive hepatosplenomegaly, and severe growth retardation. In addition, bone deformities, such as frontal bossing and maxillary prominence, gave the patients characteristic facies. Deformities of the long bones of the legs were also commonly seen and were thought to reflect severe osteoporosis. Thalassemia major, or "Cooley anemia," was and is far more common in Greece and Italy than in the United States, and descriptions of the disease in these countries soon followed Cooley's original report.[544]

Autopsy studies revealed extraordinary expansion of bone marrow at the expense of bony structures. Extramedullary hematopoiesis was often a striking feature and appeared as either isolated massive hepatosplenomegaly or hepatosplenomegaly in association with intrathoracic or intraabdominal masses.[543-545] Children were also noted to have significant iron deposition in almost all organs, the significance of which was not initially appreciated.[545] Before regular blood transfusion regimens were used, these changes progressed inexorably and were invariably fatal during the first few years of life. Patients died of the effects of their anemia: congestive heart failure, intercurrent infection, or complications resulting from all too commonly seen pathologic fractures.

Initial transfusion regimens were mainly palliative; transfusions were recommended only when the anemia interfered significantly with a patient's ability to function on a daily basis. In defense of this regimen, we must realize that the pathophysiologic basis of the disease was not understood and that clinicians first attempted to minimize the transfusional iron administered because they feared that the iron, seen ubiquitously in these patients at autopsy, might itself be the cause of the disease.[545] Palliative transfusion therapy enabled affected persons to live somewhat longer than patients who did not receive transfusions, but the bone deformities and severe anemia forced them to lead markedly restricted lives.

In an attempt to improve the quality of life of these patients, trials using routine transfusion schedules to maintain hemoglobin levels of 8.5 g/dL or greater were initiated.[546-548] The condition of patients improved dramatically, with fewer overt adverse effects of anemia and more normal growth.[549,550] Clinical improvement proved transient, however, because regular transfusions led to the complications of chronic iron overload, including growth retardation from endocrine disturbances, diabetes mellitus, and delayed sexual maturation. Death invariably ensued in the second or early third decade of life, most often as a result of iron-induced cardiac arrhythmias or intractable congestive heart failure.[551]

Pathophysiology

Imbalance in Globin Biosynthesis. That severe β-thalassemia was caused by impaired production of β-globin was established in the mid 1960s by direct measurement of globin biosynthesis in reticulocytes.[552-556] Soon thereafter, impaired production of α chains was demonstrated in the α-thalassemia syndromes.[451] Decreased hemoglobin production is reflected in the peripheral blood smear by hypochromia, microcytosis, and target cells (which are a sign of the severe impairment in total hemoglobin production), as well as by teardrops, fragments, and microspherocytes (see Fig. 21-26). Red blood cell fragmentation is a direct consequence of unbalanced globin chain synthesis. Excess α chains, which have no complementary non–α chains with which to pair, form insoluble inclusions, demonstrable on methyl violet staining of the peripheral blood of asplenic patients with β-thalassemia (Fig. 21-27). In persons who have not undergone a splenectomy, these inclusions are difficult to demonstrate because they are efficiently removed during the passage of red blood cells through the splenic sinusoids, where fragments and teardrops are generated (Fig. 21-28).

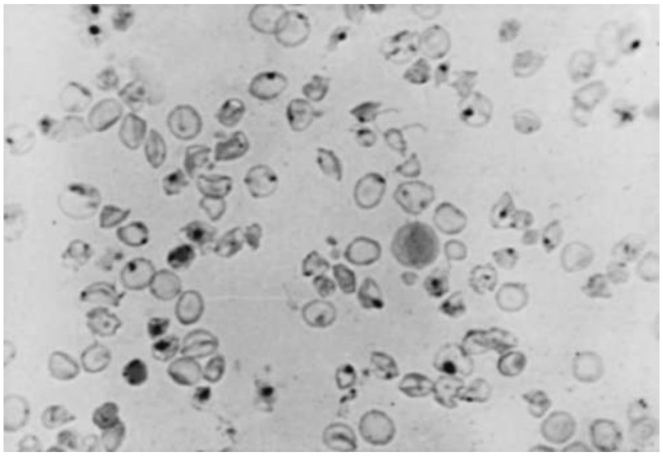

Figure 21-27 Supervital stain (methyl violet) of the peripheral blood cells from a patient with homozygous β-thalassemia after a splenectomy.

α-Globin inclusions in the erythrocytes and nucleated erythroid cells of patients with thalassemia major were first demonstrated by Fessas and colleagues[557-559] and by Nathan.[560] The incidence of the inclusions parallels the degree of impairment in β-globin synthesis. Inclusions have several deleterious effects on erythroid cells and are believed to lead to severe ineffective erythropoiesis. Intranuclear α-globin inclusions, visualized with electron microscopy, have been hypothesized to interfere with cell division.[561,562]

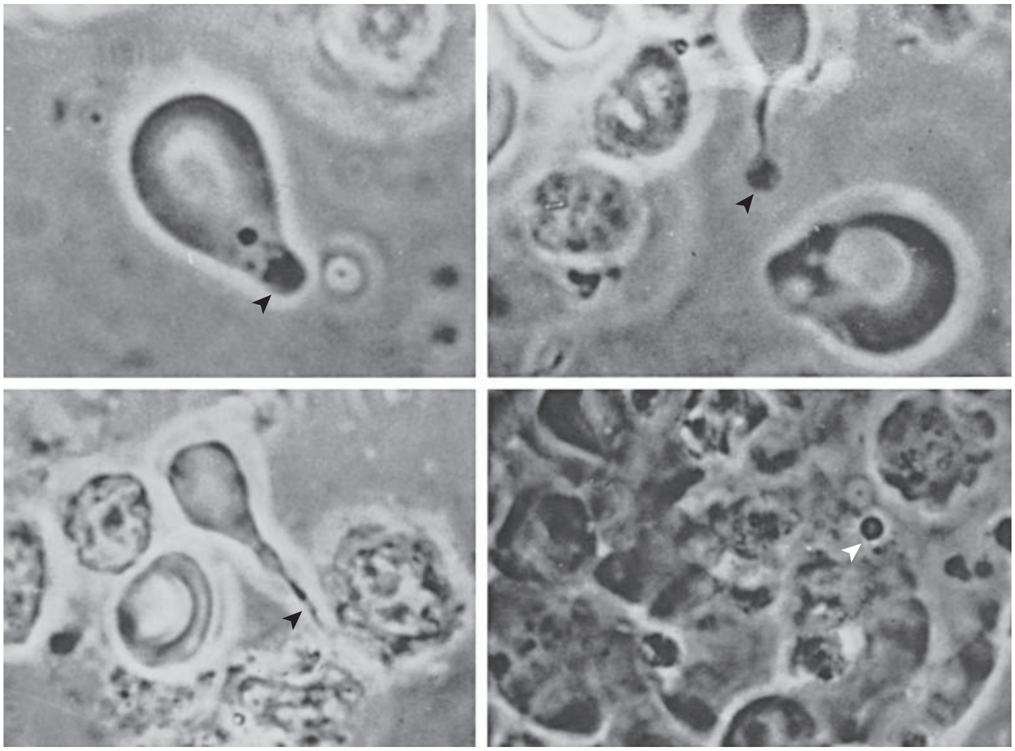

Figure 21-28 Phase-contrast microscopy of a wet preparation of scrapings from the spleen of a patient with homozygous β-thalassemia. Note the chain inclusion bodies *(black arrowheads)* within teardrop-shaped red blood cells; inclusions being pulled out, or "pitted," from the red blood cell by reticuloendothelial cell action *(lower left)*; and inclusions free in the splenic pulp *(white arrowhead)*.

Intracytoplasmic inclusions oxidize and mechanically damage cell membranes, interfere with mitochondrial function, and permit the ingress of calcium ions, which perturb the internal monovalent cationic environment and thereby contribute to the intramedullary death of erythroid cells. Moreover, α inclusions reduce red blood cell deformability and very likely interfere with egress from the bone marrow spaces, as well as from the tortuous vasculature of the spleen. The combined effects of ineffective erythropoiesis and severe anemia account for the extraordinary marrow expansion seen in patients with thalassemia major. In fact, these persons have a nonfunctional cell mass that approximates the 10^{15} tumor cells present in patients with fatal leukemia and is associated with a profound hypermetabolic state that includes fever, wasting, and hyperuricemia.[560]

The Red Blood Cell Membrane. Numerous membrane abnormalities of thalassemic erythrocytes have been described.[463,465,563] Many are attributable to oxidative damage from excess globin chains and the association of heme and iron with the cell membrane after the degradation of precipitated hemoglobin chains.[463,564] Other abnormalities may result from selective interaction of excess α or β chains with the membrane cytoskeleton. After oxidation, globin chains, as well as trace metals such as iron and copper, generate free oxygen radicals that foster oxidative injury to the membrane.[565] Peroxidation of lipids in the red blood cell membrane is reflected by altered membrane lipid composition and distribution; polymerization of membrane components caused by lipid peroxidation leads to excessive calcium influx, monovalent cation loss and dehydration, decreased cell deformability, and increased rigidity of the phospholipid bilayer.[109,110,566] Similar changes are observed in normal red blood cells forced to engulf excess α chains.[567] The reductions observed in the level of serum and red blood cell vitamin E, a natural antioxidant, may result from accelerated consumption secondary to oxidant stress. The abnormal lipid distribution may contribute to enhanced clearance by macrophages. Increased binding of autologous immunoglobulin G with an α-antigalactosyl specificity, originally proposed to reflect a decrease in sialic acid content of the membrane, may also promote clearance of thalassemic red blood cells from the circulation. The increased calcium content of thalassemic red blood cells is a hallmark of membrane damage.

Electrophoresis of red blood cell membrane proteins readily demonstrates an increased association of globin chains with the red blood cell membrane (up to 11% of total protein), and similar findings can be reproduced in nonthalassemic erythrocytes by exposure to experimental oxidative stress.[568] The α- and β-globin chains interact differently with components of the cytoskeleton.[569-571] The specificity of these interactions may contribute to the different phenotypic manifestations of the disorders. Membrane protein 4.1 of β-thalassemia erythrocytes has a diminished capacity to enhance the binding of spectrin to actin. In HbH disease, protein 4.1 appears to be normal, but binding of spectrin to inside-out vesicles is decreased, potentially because of oxidative damage to ankyrin promoted by binding of HbH to protein band 3, with which ankyrin interacts. Spectrin binding is normal in β-thalassemia erythrocytes.

Schrier and colleagues[572] reported differences in the rheologic properties of erythrocytes obtained from patients with HbH disease and β-thalassemia intermedia. Erythrocytes from both groups had a normal surface area but decreased cellular volume and increased membrane rigidity that resulted in decreased cellular deformability under conditions of hypertonic osmotic stress. Although HbH erythrocytes exhibit an increase in mechanical stability and a decrease in cell density, β-thalassemia erythrocytes are prone to cellular dehydration and have markedly decreased mechanical stability. In a murine model of β-thalassemia, these cellular abnormalities correlated with the extent of α-globin associated with the membrane; small increases in β-globin chain expression through the introduction of a β-globin transgene resulted in a marked decrease in membrane-associated globin and significant reversal of the rheologic abnormalities.[573] Thus the slight improvements in chain synthetic balance that accompany increased expression of γ-globin or decreased expression of α-globin may result in dramatic improvements in membrane integrity in patients with β-thalassemia. More detailed understanding of the red blood cell membrane abnormalities in thalassemia may facilitate the development of novel therapies in the future.

Genetic Heterogeneity. In current hematologic parlance, the term *thalassemia major* refers to patients with severe β-thalassemia who require regular blood transfusions to sustain life. In the vast majority of such patients, both β-globin genes are affected by a thalassemia mutation; hence they are described as homozygous β-thalassemics, although in the United States most are actually double heterozygotes. In other patients who also appear to be homozygous for β-thalassemia mutations based on family studies, a hemoglobin concentration of 6 to 10 g/dL is maintained without blood transfusions except during periods of infection, surgery, or other stress.[1,574] Such patients are said to have *thalassemia intermedia*. Thalassemia intermedia is a clinical term that describes the transfusion status of the patient. The term *Cooley anemia* is still often used and applied somewhat indiscriminately to individual patients with either the major or intermedia clinical syndrome. Although other acquired and genetic modifiers exist, disease severity in the β-thalassemias is most directly related to the degree of imbalance between α- and total non–α-globin synthesis. Three major factors emerge as important determinants of the biosynthetic ratio in individual patients: the nature of the specific mutation or mutations, the presence of abnormalities in the α-globin cluster that increase or decrease α-globin expression, and the genetic capacity for synthesis of HbF. Proteolysis of excess α chains, evident on comparison of the α to non-α biosynthetic ratio by short- and long-term incubation of bone marrow cells[490-494] (discussed earlier), is also likely to modulate disease severity, although no meaningful quantitative studies of this mechanism have yet appeared. Recently, a chaperone of free α-globin chains has been described (discussed earlier).

Nature of Specific Mutations. The capacity for production of β-globin chains in a person with thalassemia is directly determined by the specific mutations involving the β-globin gene. Because several different mutations are commonly found in populations with a high incidence of β-thalassemia, most American patients with clinical homozygous β-thalassemia are heterozygous for two different mutations. The effect of specific mutations may range from total loss to only a mild impairment in β-globin synthesis, and thus the potential interactions based on the many different mutations are extraordinary. Indeed, disease severity may be viewed as a continuum, the extremes of which have been shown to correlate with specific mutations.

Mutations in the IVS-1 splice donor site (see Table 21-2 and Fig. 21-10) provide a particularly illustrative example of the variable consequences of specific mutations on β-chain synthesis. These mutations lead to either a complete block in correct splicing of β-globin mRNA or merely a reduction in the abundance of normal mRNA. Patients homozygous for a mutation in the conserved GT splice junction dinucleotide and who have not co-inherited an α-thalassemia gene or a determinant that increases HbF synthesis display severe transfusion-dependent β^0-thalassemia.[149,158-160] Substitution of C or T at position 5 of the splice donor consensus sequence results in severe β^+-thalassemia,[131,158,169-171] whereas substitution of A at the same position results in a more mild phenotype.[172] The T→C substitution at position 6 is also associated with mild β^+-thalassemia.[149]

Dominant β-Thalassemia. In rare circumstances, the heterozygous state of β-thalassemia may be associated with severe disease rather than typical thalassemia trait. Several pedigrees with severe heterozygous β-thalassemia characterized by splenomegaly, cholelithiasis, and leg ulcers have been described.[575,576] A striking association has been noted between mutations involving exon 3 of the β-globin gene and these unusual cases of dominantly inherited β-thalassemia.[251,255] Third-exon mutations typically lead to the production of an unstable β-globin chain. A subset of third-exon β-thalassemia mutations are associated with the presence of inclusion bodies in the normoblasts of affected heterozygotes (see Table 21-2)[253-257] and were first reported as "inclusion-body β-thalassemia," originally defined as a dominantly inherited dyserythropoietic anemia.[577,578] The inclusion bodies, which may contain both α-globin and β-globin, represent an aggregation of precipitated α-globin and unstable β-globin chains with the cell membrane, where they presumably potentiate oxidative damage. The dominantly inherited β-thalassemias are relatively rare and are found in ethnic groups from nonmalarious regions.[251,255] Presumably, there is little selective pressure for these mutations because of the decreased fitness of heterozygous persons.

Increased production of α-globin chains above normal levels may exacerbate the chain imbalance in β-thalassemia heterozygotes; co-inheritance of triplicated α-globin gene chromosomes is another potential cause of severe heterozygous β-thalassemia, and patients usually have the phenotype of thalassemia intermedia.[413,414,579-581]

Interaction with Genetic Determinants That Increase Hemoglobin F Synthesis. Deletions within the β-globin gene cluster and mutations in the γ-globin promoters are sometimes associated with increased expression of γ-globin (see earlier discussion). Relatively small, genetically determined heterocellular increases in HbF ameliorate the clinical course of thalassemia,[112,113,354,366,516,582] thereby raising the prospect that pharmacologic augmentation of γ-chain production may be of particular benefit in the management of thalassemia (discussed later).

An apparent amplification of the capacity for HbF synthesis during erythroid maturation is readily demonstrated in thalassemic patients. In the earliest erythroid precursor cells, γ-globin may be synthesized at a level less than that of β-globin and at only a small percentage of that of α-globin, yet the final proportion of HbF in patients not receiving transfusions may be quite high.[1,109] This effect occurs because the subset of cells expressing γ-globin have less overall globin chain imbalance and therefore preferentially survive in both bone marrow and peripheral blood; hence measurement of steady-state HbF levels provides an imperfect measure of the capacity for γ-globin synthesis in individual patients. More accurate assessment of the HbF program is achieved by measurement of the HbF accumulated in progenitor-derived erythroid colonies produced in vitro.[583]

Interaction of α- and β-Thalassemia Mutations. Because the clinical severity of α- and β-thalassemia correlates with the degree of imbalance in the production of α and non-α chains, co-inheritance of α- and β-thalassemia mutations would be anticipated to yield syndromes of intermediate severity.[584-590] This principle has been validated by clinical experience.[116,591,592] One striking example is the influence of the number of functional α genes in persons with β-thalassemia trait in Sardinia.[116] As shown in Table 21-9, MCV and MCH improve in a stepwise fashion as α-globin production decreases and the α-globin to β-globin ratio approaches 1, but they then deteriorate as the ratio decreases to less than 1. This analysis provides conclusive evidence that the degree of chain synthesis imbalance determines the red blood cell phenotype. Thus a higher incidence of α-gene deletions (–α/αα or –α/–α) has been found in patients with thalassemia intermedia than in patients with thalassemia. Further evidence for the effect of α-gene number on clinical phenotype is the occurrence of thalassemia intermedia in a subset of persons doubly heterozygous for β-thalassemia and triplicated α genes (ααα/αα)[413,521,579-581] or severe β-thalassemia trait in persons also heterozygous for triplicated α genes.[570,571,593-599] Persons heterozygous for β-thalassemia but homozygous for triplicated α genes invariably have thalassemia intermedia.

Clinical Features and Laboratory Values on Initial Evaluation. Severe β-thalassemia is most often diagnosed between 6 months and 2 years of age when the normal physiologic anemia of the newborn fails to improve. γ-Globin production is not impaired in utero; therefore, only when β-globin becomes the predominant β-like globin

TABLE 21-9 Effect of Successive α-Globin Gene Deletion on Hematologic Parameters in a Homogeneous Population with β-Thalassemia Trait

Group/Genotype	Hb (g/dL)	MCV (mm^3)	MCH (pg)	HbA$_2$ (%)	HbF (%)	Ratio
αα/αα (*n* = 20)	12.4 ± 1.2	66.2 ± 3.7	21.2 ± 1.2	4.8 ± 0.7	1.4 ± 1.3	2.2 ± 0.3

does anemia ensue. Occasionally the disease is not recognized until 3 to 5 years of age because prolonged HbF synthesis compensates for the lack of HbA. When first seen, affected infants usually display pallor, poor growth, and abdominal enlargement from hepatosplenomegaly.

Children with severe β-thalassemia are readily distinguished from children with other congenital hemolytic anemias. At initial evaluation, patients who have not received transfusions show 20% to 100% HbF, 2% to 7% HbA$_2$, and 0 to 80% HbA (see Fig. 21-23), depending on the precise genotype. Consistent with severe ineffective erythropoiesis and splenomegaly, the reticulocyte count is characteristically low (often <1%), whereas the nucleated red blood cell count is elevated. Erythrocytes are severely microcytic (MCV of 50 to 60 μm^3) with a hemoglobin content as low as 12 to 18 pg/cell. HbF can be shown to be heterogeneously distributed among the red blood cells either by the Betke-Kleihauer acid elution technique or by anti-HbF fluorescent staining (see Fig. 21-19).

Bone marrow examination reveals marked erythroid hyperplasia, often with an erythroid-to-myeloid cell ratio of 20 : 1 or greater. Before the onset of hypersplenism, the accelerated rate of hematopoiesis may also be reflected by elevated white blood cell and platelet counts in peripheral blood. The serum iron value is markedly elevated, but total iron-binding capacity is usually only slightly increased, thereby resulting in a transferrin saturation of 80% or greater. Serum ferritin levels are generally elevated for age.

If laboratory parameters fail to establish the diagnosis of thalassemia, demonstration of a mild microcytic and hypochromic anemia, indicative of the presence of thalassemia trait in both parents, will allow the diagnosis to be made with confidence. If the diagnosis remains in doubt, it can be confirmed by globin genotyping.

Complications

The cause of the complications of thalassemia is multifactorial and variable and depends on the genotype, other known and unknown phenotypic modifiers, and availability and adherence to therapy. The pathophysiologic features of the complications stem from ineffective and extramedullary hematopoiesis and treatment-related adverse effects, including transfusional iron overload, transfusion-associated infections, and chelation. In addition, more recently recognized but not fully understood is the increased risk for clinically evident and silent thromboses leading to pulmonary hypertension and overt portal vein thromboses. The complications of thalassemia in a large group of North American patients have recently been reviewed.[600]

Bones. To appreciate the full spectrum of bone changes in persons with severe β-thalassemia, one must examine patients who receive transfusions rarely.[542,543] Bone disease in such patients is primarily related to erythroid expansion and not to iron overload or abnormalities in vitamin D metabolism.[601,602] Maintenance of nearly normal hemoglobin levels results in suppression of erythropoiesis and tends to reverse the bone abnormalities,[570,571,593-599,603-605] but osteoporosis is common even in patients who receive regular transfusions.[606-609] Some clinics report a high incidence of vertebral compression fractures.[608] A recent review of more than 700 patients with thalassemia syndromes reported an overall fracture prevalence of 12.1% that ranged from 2.5% in very young patients to 23% in patients older than 20 years. Therapy with excessively high doses and sometimes even standard doses of deferoxamine may also lead to metaphyseal dysplasia.[610-612]

Radiologic abnormalities may be present during the first 6 months of life but are not usually marked until about 1 year of age.[613] In the small bones of the hands and feet the trabecular pattern is coarse, cystic abnormalities are present, and the bones are tubular in appearance. The long bones of the extremities exhibit thinning of the cortices and marked dilation of the medullary cavities. Accordingly, they become extremely fragile and prone to pathologic fractures.[614] The skull is also classically involved, with marked widening of the diploic space and arrangement of the trabeculae in vertical rows, which tends to give a "hair on end" appearance to the skull radiograph (Fig. 21-29). Other radiologic abnormalities in the skull include failure of pneumatization of the maxillary sinuses and overgrowth of the maxilla. These changes lead to maxillary overbite, prominence of the upper incisors, and separation of the orbits—changes that contribute to the classic "thalassemic facies."

Other bone changes caused by medullary overgrowth include widening of the ribs with notching and the development of masses of extramedullary hematopoietic tissue, which may appear as tumors in the chest and mediastinum.

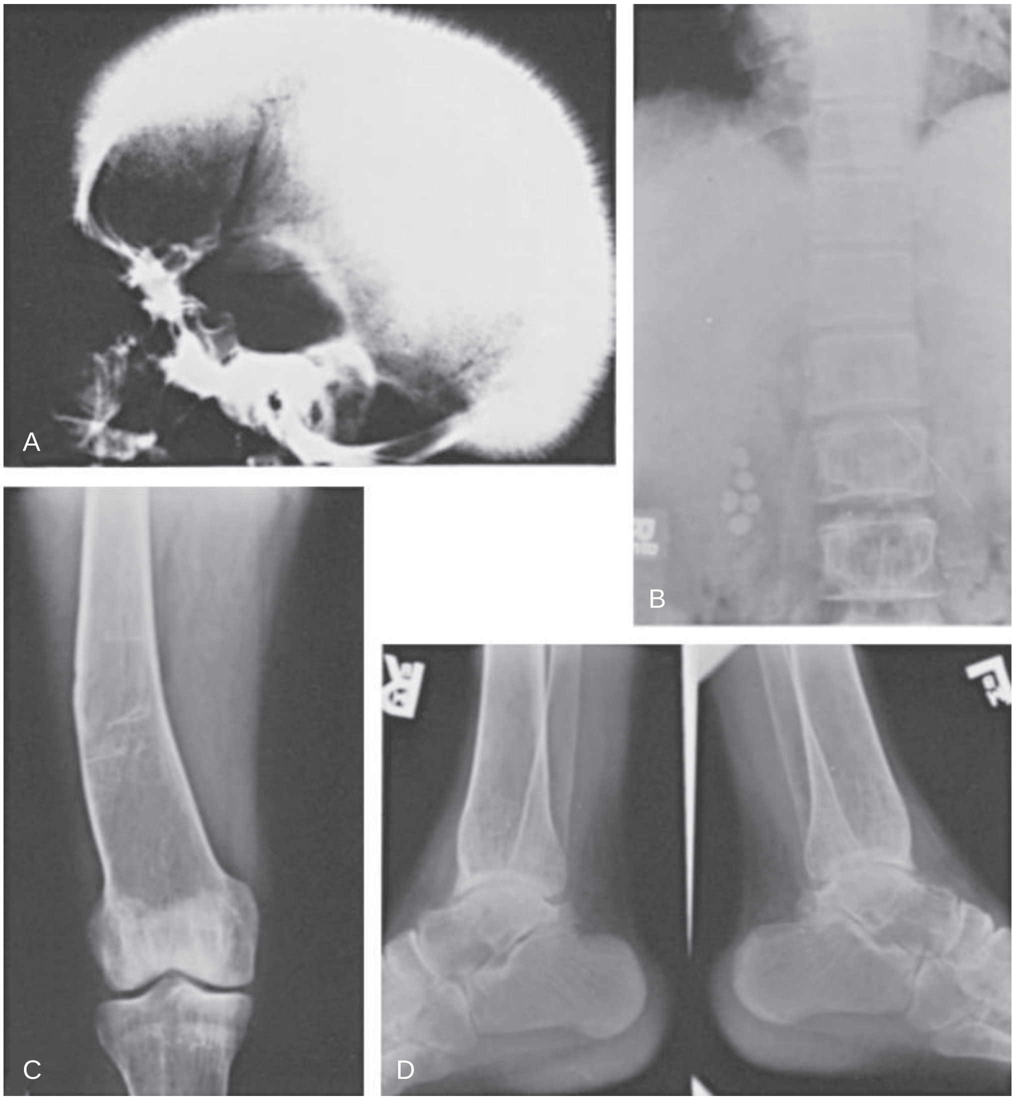

Figure 21-29 Radiologic abnormalities in a patient with homozygous β-thalassemia who receives blood transfusions rarely (thalassemia intermedia). **A**, A skull radiograph illustrating the typical "hair on end" appearance of the diploë and failure of pneumatization of the frontal sinus. **B**, An abdominal film illustrating the coarse trabeculation and osteoporosis within the vertebrae. Multiple calcified gallstones are also seen. **C**, Severe osteoporosis, pseudofractures, thinning of the cortex, and bowing of the femur. **D**, Degenerative arthritis affecting the tibiotalar joint in particular is reflected by loss of the cartilage space and sclerosis in the adjacent bone.

The vertebrae are square with coarse trabeculae. The aforementioned osteoporosis and associated bone pain may be relieved by calcitonin therapy,[615] but the role of vitamin D and calcium supplementation in the prevention of osteoporosis in patients with thalassemia has not been established. Controlled randomized studies have revealed the potential value of bisphosphonate therapy to improve bone density as measured with bone density scans.[616]

Gallbladder. Calcium bilirubinate gallstones resulting from excessive excretion of the products of heme catabolism are common in older patients.

Iron Deposition. A detailed discussion about iron deposition and treatment options is found in the subsequent section on Therapy for β-Thalassemia.

Therapy for β-Thalassemia

Transfusion

Choice of Transfusion Regimen. The mainstay of management of severe β-thalassemia remains blood transfusion.[617-624] Transfusion programs have several aims. By increasing the hemoglobin content, transfusions enhance the oxygen-carrying capacity of blood and thereby decrease tissue hypoxia. The concomitant decrease in erythropoietin levels blunts the massive erythroid expansion associated with the anemia. Furthermore, improved tissue oxygenation and reversal of the hypercatabolic state promote more normal growth and development. Suppression of erythropoiesis is associated with decreased intestinal iron absorption. These benefits must be weighed against the prospects of excessive iron loading, particularly with more intensive transfusion protocols.

Transfusion management and the optimal maintenance level of hemoglobin have evolved. Wolman and associates[546,625] first recommended a pretransfusion hemoglobin level of 8.5 g/dL. This approach improved survival, but chronic illness, bone disease, and anemic cardiomyopathy persisted. To enhance quality of life, Piomelli and colleagues[550] suggested maintaining the hemoglobin level at greater than 10 g/dL with a mean of 12 g/dL. Such "hypertransfusion," if initiated in the first year of life, promotes normal initial growth and development, limits the development of hepatosplenomegaly, prevents disfiguring bone abnormalities, reduces intestinal iron absorption, and decreases cardiac workload.[626-629]

In 1980, Propper and colleagues[630] proposed a "supertransfusion" program with a pretransfusion hemoglobin level greater than 12 g/dL and a mean of 14 g/dL to more effectively eliminate chronic tissue hypoxia. Initial studies reported that the quantity of blood required to maintain a higher hemoglobin level was no greater than that required for maintenance of a lower level because of a decrease in intravascular volume.[630-632] Further data, however, suggested that increasing the pretransfusion hemoglobin level may simply increase the quantity of transfused blood and thus increase iron loading,[633,634] and this regimen is no longer recommended.

Senescence in red blood cells is a function of cell age. Because the iron content of transfused erythrocytes is independent of cell age, attempts have been made to improve the "quality" of transfused blood by infusing the youngest third of red blood cells present in whole blood ("neocytes").[629,635] Administration of these cells would be predicted to decrease the transfusion requirement. Neocytes can be readily prepared with automated cell separators,[636-640] but 3 or more units is required to prepare the equivalent of 1 unit of blood, thus drastically increasing donor exposure for these patients. Although prolonged survival of neocytes has been documented in vivo, the observed sparing of transfusions with such therapy has been disappointing.[641-644] Similarly, methods to remove "gerocytes" (old red blood cells) from the recipient's circulation at the time of transfusion, although technically feasible, have not been widely applied.[643,645] These approaches should be considered experimental at present.

Although specific practices differ among clinical centers, transfusion is indicated both to correct anemia and to suppress erythropoiesis.[617] After diagnosis, a period of observation should be initiated to determine whether transfusion is required to maintain the hemoglobin level at 7 g/dL or greater. The condition of patients with thalassemia intermedia will be stable without transfusion. If the hemoglobin level decreases to less than 7 g/dL, a transfusion program should be initiated to maintain the hemoglobin level at 9.5 to 11.5 g/dL. During the first decade of life, normal growth provides reassurance that the transfusion regimen is adequate. Because the rate of iron absorption parallels the number of nucleated red blood cells in peripheral blood,[646] adequate transfusion should suppress the nucleated cell count to less than 5 per 100 white blood cells[617]; however, in older patients who received inadequate transfusion therapy early in life, it may not be possible to achieve this level. During the teenage years, growth failure may reflect endocrine dysfunction rather than inadequate transfusions; laboratory investigation and appropriate replacement therapy are then indicated. After the epiphyses have fused and growth is complete, a hemoglobin level of 8.0 to 9.0 g/dL may be well tolerated. If the transfusion requirement exceeds 200 mL of packed red blood cells per kilogram per year, splenectomy should be considered (discussed in more detail later).[617] Our current transfusion procedure is outlined in Box 21-1.

Box 21-1 Guidelines for Chronic Transfusions in Patients with Thalassemia

1. Determine the blood type of the patient completely to identify minor red blood cell antigens before the first transfusion.
2. Keep the pretransfusion hemoglobin level between 9.5 and 11.5 mg/dL as needed for suppressing ineffective erythropoiesis and maintaining a reasonable sense of well-being.
3. Give 10 to 20 mL/kg of leukocyte-poor, washed, and filtered red blood cells at a maximum infusion rate of 10 mL/kg over a 2-hour period; transfuse more slowly in patients with heart disease.
4. Avoid raising the posttransfusion hemoglobin level to greater than 16 g/dL.
5. Choose a transfusion interval to maintain pretransfusion levels as outlined above (3 to 5 weeks, depending on individual patient needs). (*Comment*: Some patients tolerate slightly lower pretransfusion hemoglobin levels and need 5 weeks between transfusions, whereas others feel best when they receive a transfusion every 4 weeks. Some patients prefer receiving fewer units and coming every 3 weeks. Some of the younger patients whose weight would require between 1 and 2 units receive a transfusion every 3 or 4 weeks and alternate between 1 and 2 units per transfusion.)
6. Pretransfusion laboratory tests include a complete blood cell count, differential, crossmatch, and red blood cell antibody screen.
7. Height and weight are recorded at least every 3 months.
8. Liver function (AST, ALT, bilirubin, and LDH) is evaluated every 3 months, and serum ferritin is evaluated every 3 to 6 months. A deferoxamine (Desferal) challenge test is performed at irregular intervals to measure the appropriate Desferal dosage and chelatable iron stores.

ALT, Alanine transaminase; *AST,* aspartate transaminase; *LDH,* lactate dehydrogenase.

Complications of Blood Transfusion. The primary long-term complication of blood transfusion is iron loading and the resultant parenchymal organ toxicity, as discussed earlier. Febrile reactions to leukocyte antigenic determinants and allergic reactions to plasma components are commonly encountered in patients who receive transfusions on a long-term basis. The use of prestorage leukoreduction filters has significantly decreased the rate of febrile reactions. Washing of red blood cells in saline solution to remove plasma proteins can be beneficial.[647]

Alloimmunization to minor blood group antigens occurs in 20% to 30% of patients[648-651] and may be manifested as delayed hemolysis. Rare circumstances of multiple alloantibodies may be a potentially life-threatening complication in patients with transfusion-dependent β-thalassemia because it may not be possible to find sufficient appropriately matched blood. Alloimmunization is frequently a less significant problem in patients in whom transfusion is initiated before the age of 3 years.[648-651] The benefit of extended red blood cell phenotyping to minimize alloimmunization has been debated in the literature,[652,653] but crossmatching for the rhesus and Kell systems from the time of initial transfusion may decrease the incidence of alloimmunization.[650] Detailed red blood cell phenotyping should be performed in all patients with newly diagnosed thalassemia before transfusion. The average transfusion regimen in most centers is 12 to 15 mL of leukocyte-poor red blood cells per kilogram per month. Autoimmune hemolytic anemia is a rare but perilous complication of allosensitization. It must be managed aggressively to prevent dangerous iron overload.

Transmission of viral infections by transfusion remains a serious and significant problem in patients receiving transfusions on a long-term basis in countries in which the safety measures of volunteer donors, detailed donor questionnaires, and serologic and nucleic acid testing are not used. In one study, approximately 25% of transfusion-dependent patients with thalassemia had been exposed to hepatitis B, 80% of whom had clinical evidence of hepatitis.[654] Exposure to hepatitis C, with an incidence of approximately 6% per transfusion, was nearly inevitable in thalassemic patients receiving regular transfusions, and this agent accounts for the active hepatitis seen in many older patients. Identification of the hepatitis C agent and the development of a serologic test to screen donors have greatly minimized this risk,[655,656] but the infection can lead to fibrosis, cirrhosis, and hepatic carcinoma if untreated.[657-659] Treatment with interferon alfa and ribavirin is indicated and has now been demonstrated to be safe in patients with thalassemia despite the increased rate of hemolysis and transfusion resulting from the administration of ribavirin.[660] Some studies have suggested that iron overload inhibits a therapeutic response,[661-664] but others have shown little or no such effect.[665,666] A minority of patients with thalassemia have become infected with human immunodeficiency virus, and the rate of progression to symptomatic acquired immunodeficiency syndrome has been proportionately lower than in most infected populations.[667] Although death and complications from these illnesses are uncommon in this patient population, it is prudent to exercise precautions. The most important consideration is the use of blood products screened for the presence of potential infectious agents. Patients should be immunized against hepatitis B upon diagnosis or if they have not acquired immunity. When practical, exposure to multiple donors or units of blood should be minimized. In this regard it is important to recognize that the use of washed or frozen red blood cells may lead to an increase in the number of transfused units.

Splenectomy. Splenectomy may be indicated in some patients in an attempt to decrease transfusion requirements. The role of the spleen must be carefully considered in patients who are treated with transfusion, iron chelation programs, or both. The spleen serves both as a scavenger by increasing red blood cell destruction and iron redistribution and as a storage depot by sequestration of the released iron in a potentially nontoxic pool. Unfortunately, splenic iron may equilibrate with other iron pools throughout the body. In one uncontrolled study, three patients who had undergone a splenectomy exhibited cirrhosis and massive iron deposition, whereas slightly younger patients with an intact spleen had only iron deposition.[668] Risdon and colleagues,[669] however, observed no difference between patients who had and had not undergone a splenectomy with regard to pathologic changes in the liver. If the spleen acts primarily as a storage depot for excess iron, premature removal could theoretically be detrimental. On the other hand, if the splenic pool is a particular target for deferoxamine, the beneficial effects of aggressive chelation therapy might be diminished by preferential removal of iron from this relatively innocuous pool. Perhaps most important is the feasibility of achieving negative iron balance with conventional chelation regimens (discussed later). Eventually, an increased requirement for transfusion because of hypersplenism perturbs the balance and contributes to iron loading.[670]

Splenectomy may be indicated in the management of patients with severe β-thalassemia. Massive splenomegaly with hypersplenism causing leukopenia, thrombocytopenia, and an increasing transfusion requirement is often seen in young patients whose transfusion regimens are sporadic. Early splenectomy is often required. The development of splenomegaly is delayed in patients who are receiving a high number of transfusions.[671] Several factors should be considered in the decision to remove the spleen. Modell and Berdoukas[633] and Modell[672,673] carefully documented the annual blood requirement of patients with thalassemia major who had undergone a splenectomy and suggested that the spleen be removed if the observed requirement exceeds that predicted by 50%. Data from other investigators suggest that the benefits of splenectomy with regard to iron balance are realized if the transfusion requirement exceeds 200 to 250 mL of packed red blood cells per kilogram per year with a minimum hemoglobin level of 10 g/dL.[670,674] Because a huge spleen, irrespective of functional hypersplenism, may account for a large fraction of the total blood volume, its removal often leads to a marked though transient reduction in the patient's requirement for blood.[675,676] Most patients show a moderate but significant reduction in their requirement for transfusion to the predicted 200 mL of packed red blood cells per kilogram per year,[672,673] and it remains stable for many years.[677]

The immediate surgical risk accompanying splenectomy is minimal for experienced practitioners, although reports of acute portal vein thrombosis are increasingly being recognized. Some evidence indicates that iron overload itself may inhibit the immune response.[678,679] Infections with *Yersinia* are sometimes observed in patients with iron overload.[680] The potential for overwhelming infection by *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Neisseria meningitidis*[681-683] should always be considered by the attending physician. Because removal of the spleen may blunt the primary immune response to encapsulated organisms, delay of splenectomy until after approximately 5 years of age is preferable. Patients should be immunized with polyvalent pneumococcal, meningococcal, and *H. influenzae* vaccines.[684-687] Supplemental prophylactic oral penicillin may also be used to prevent colonization by strains not covered by vaccines,[617] particularly in young children. Illnesses accompanied by high fever of uncertain cause should be treated aggressively with parenteral antibiotics until bacterial culture results are available. Patients in regions endemic for malaria should receive prophylactic treatment.[673] Infections appear to be significant causes of morbidity in HbE–β-thalassemia.[688]

Red blood cell survival usually increases immediately after a splenectomy.[675] The peripheral blood smear may reveal increased numbers of hypochromic, microcytic, and nucleated red blood cells. Platelet counts greater than 10^6 are often seen, although correction of anemia by transfusion generally results in suppression of platelet production.[469] White blood cell counts of 15,000 to 20,000 are common; the differential is usually normal.

As was previously discussed in more detail, arterial hypoxemia and evidence of pulmonary vascular disease have been reported in patients with thalassemia, and it has been suggested that splenectomy may exacerbate these problems.[689,690] Accordingly, patients who have undergone a splenectomy should be examined carefully for these findings. Because thrombocytosis may be an inciting factor,[690,691] prophylaxis with low-dose aspirin may be considered, although effective transfusion to correct anemia is probably the best form of preventive therapy.

Therapy for Iron Overload. The economy of iron in the human is discussed in detail in Chapter 11. Briefly, the growing child slowly accumulates iron from his or her diet, using about two thirds for hemoglobin production and one tenth for various enzymes and myoglobin; the remainder is held in storage for later use, largely as ferritin in hepatocytes and macrophages.

Although iron is essential for metabolism and oxygenation, its reactivity would be lethal were it not tightly bound to protein. Nonheme iron is an essential cofactor in many hydroxylases and dioxygenases, and heme iron is required for the function of cytochromes and hemoglobin. "Free" iron (i.e., iron that is unbound to hemoglobin, enzymes, or transport or storage proteins) participates in the generation of reactive oxygen species that rapidly oxidize lipids, nucleic acids, and proteins, injuring cell membranes as well as vital enzymes. To counteract the potential reactivity of excess iron, the absorption of iron from the gastrointestinal tract is limited to daily iron losses and incremental amounts required for growth. Iron is absorbed entirely in the duodenum. The mechanism of absorption of heme iron (largely from meat) is not thoroughly understood. In any case, heme iron absorption is independent of and much more efficient than the absorption of nonheme iron, which must first be reduced to the ferrous form and then transported by a divalent metal transporter called DMT1 on the brush border. Iron from both sources is then transported from the intestinal cell via ferroportin at the basolateral surface into the portal blood. This definitive systemic absorption step is negatively regulated by the peptide hormone hepcidin, which is synthesized in the liver and induced by iron adequacy/overload. Failure of this hepcidin-ferroportin axis is associated with the genetic disorder hereditary hemochromatosis in which the liver produces insufficient hepcidin for the degree of iron overload. Importantly for the discussion of the pathophysiology of non–transfusion-dependent thalassemias, hepcidin synthesis is also dysregulated by anemia, particularly the forms of anemia that are characterized by severe ineffective erythropoiesis. The signal that mediates this link between anemia, the rate of erythropoiesis, and the regulation of hepcidin is presently unknown.

Rate and Extent of Iron Overload. Patients with thalassemia intermedia who have not received transfusions slowly but inexorably accumulate iron from their diets because, in persons with this condition, the level of hepcidin released by the liver is inappropriately low.[692] This complication and its consequences are discussed in more detail below. Patients with severe thalassemia who have received transfusions have high serum levels of hepcidin and consequently do not absorb excess iron from their diets.[692] However, every milliliter of transfused red blood cells contains 1 milligram of iron, and only a tiny fraction of the transfused iron is eliminated in the form of shed skin and intestinal mucosa. Hence the accumulation of iron in epithelial and storage cells in nearly every organ but bone and skeletal muscle, as well as high non–transferrin-bound plasma iron (NTBI), is rapidly progressive, and the complications of iron-induced organ dysfunction are inexorable.[693] As the iron accumulation approaches 15 to 20 g (15 to 20 L of red blood cells), symptoms of iron-induced oxidative tissue damage are nearly universal. Liver damage with cirrhosis, cardiac failure and arrhythmia, diabetes, and endocrine failure (including pituitary, thyroid, and parathyroid insufficiency) are inevitable, and death usually ensues before the age of 18 years in patients who do not undergo chelation. Demise occurs much earlier in patients with growth retardation who do not undergo transfusion or in patients who receive inadequate transfusion; these patients die of heart failure and endure marked bony deformities, particularly facial deformities as a result of massive marrow expansion, before they finally succumb. Acknowledgement of this dilemma influenced a 1960s decision[694] to maintain near-normal hemoglobin levels in transfused patients, recognizing that although disfigurement and a miserable quality of life could be ameliorated, death from iron overload would be assured unless effective chelation could be developed.

Measurement of Iron Overload. Measurements of fasting serum iron and transferrin saturation can be useful in the initial evaluation of iron overload but do not provide an index of the extent of overload. Serum ferritin (actually apoferritin) is also useful but only bears a linear relationship to the liver iron content at low levels of excess iron burden.[695] Ferritin level measurement is useful to determine the effects of chelation therapy.[696]

Until well into the 1980s, the only reliable approach to assessment of iron overload in organs was by quantitative analysis of iron content in a liver biopsy. Unfortunately, liver biopsy does not deserve the "gold standard" that was assigned to it because the hepatic fibrosis that characterizes iron overload causes a spuriously low iron content per milligram of liver tissue. Therefore iron content in the liver from one biopsy specimen to another in a single liver may be highly variable.

The development and application of the superconducting quantum interference device (SQUID susceptometer) in a tiny handful of centers (at Case Western Reserve and Columbia Universities in the United States by Gary Brittenham and his colleagues)[697] did permit a noninvasive analysis of total liver iron, but the equipment is so costly and difficult to use and occupies so much space that it never became widely adopted. Furthermore, the reproducibility of the measurements in a single patient studied with use of different machines is less than reassuring. Nonetheless, much information on the rate of iron loading and the relationship of liver iron load to morbidity and mortality was gained by the few groups that used the machines. Measurements of the effects of phlebotomy after successful stem cell transplant for thalassemia were particularly illuminating.[698]

The most useful advances in organ iron measurement have been those provided by St Pierre and colleagues[699] for assessment of hepatic iron and by Anderson and colleagues[700] with respect to cardiac iron. These magnetic resonance imaging (MRI)-based methods have been assessed in experimental animals and found to be reliable indicators of total organ iron by Wood and colleagues.[701] The relationship of the MRI signal to liver iron is much tighter at lower levels of hepatic iron than at the very high levels observed in poorly chelated patients. The techniques can be applied by skilled MRI technologists wherever the instruments can be suitably employed and if the computational programs developed by St Pierre and others are carefully applied. They are potentially applicable worldwide, as long as appropriate MRI is available. Appropriate evaluation of chelation therapy demands repeated measurements of both hepatic and cardiac iron. The two measurements may be dyssynchronous because iron kinetics are faster in the liver than in the heart during chelation. The measurement of NTBI may provide a better index of impending cardiac damage than MRI.[701a]

Iron Chelation Therapeutics[702]

Deferoxamine. Hope for a successful iron chelator began in the 1950s with the studies of Neilands,[703] who showed that a class of compounds he called siderophores were responsible for the extraction of iron from soil by prokaryotes. Influenced by Neilands' work, Heinrich Keberle, of what was then Ciba-Geigy Pharmaceuticals (now Novartis), discovered deferoxamine in soil samples.[704]

Deferoxamine (Fig. 21-30) is a hexadentate, highly selective iron chelator with an affinity constant for iron that exceeds that of transferrin. One molecule of deferoxamine binds one molecule of iron. The drug is amazingly nontoxic in the presence of high iron stores. Patients who undergo a great many transfusions can and do receive grams of the drug daily for decades without serious toxicity in the vast majority of cases. The major toxicity results from uneven depletion of iron stores and an excess of free deferoxamine in certain tissues. The latter scavenges essential iron and thereby produces various (and sometimes serious) toxicities. Both hearing loss and vision impairment are thought to be related to deferoxamine administration in some patients.[705]

Chelation of iron by deferoxamine converts the molecule into feroxamine, a circular red compound. Approximately half is excreted in the bile and half is excreted in

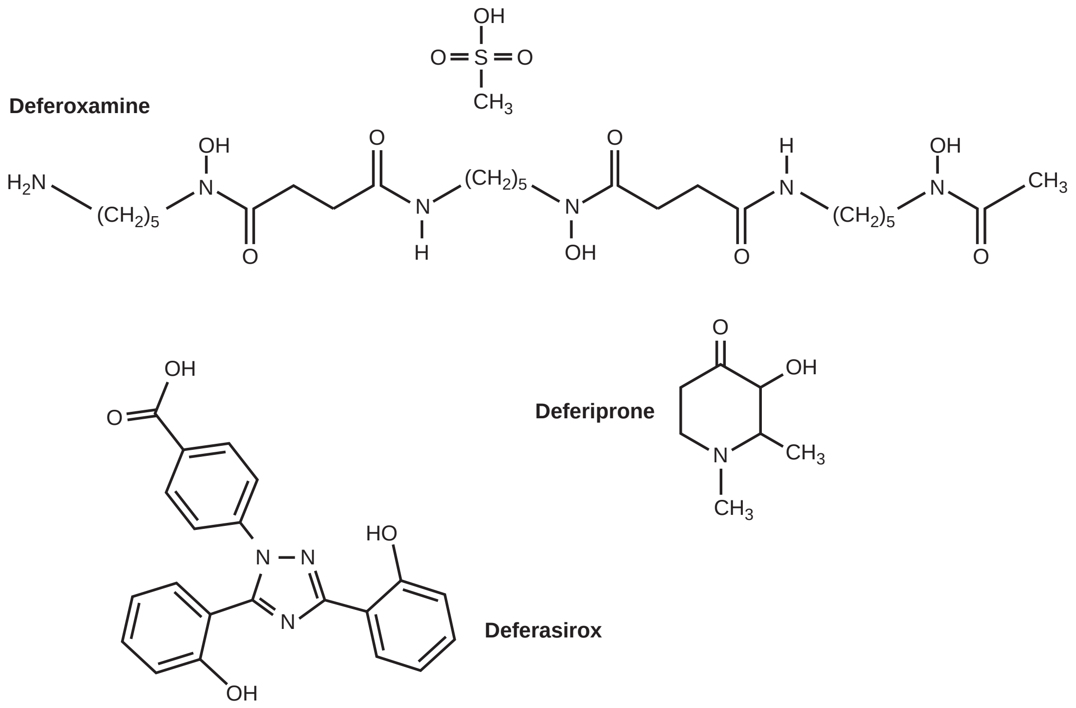

Figure 21-30 Chemical structures of the iron chelators deferoxamine, deferiprone, and deferasirox.

the urine, and thus compliance can be evaluated by simple inspection of urine color. However, the drug has serious drawbacks. It penetrates cells very slowly and is barely if at all absorbed from the gastrointestinal tract. It is rapidly cleared from the blood into stools and urine with a very short half-life of less than 30 minutes. Therefore the drug must be administered parenterally.

Although the introduction of deferoxamine in the early 1960s was enthusiastically greeted by hematologists, it soon became apparent that intramuscular administration of the drug was poorly tolerated by patients. However, Letsky and colleagues,[706] persisted and clearly showed that repeated intramuscular injection of the drug at sufficiently high and frequent doses could lead to diminution of liver iron content and reduced hepatic fibrosis in patients with thalassemia who undergo multiple transfusions. Still, the drug was poorly accepted as a therapeutic agent until the 1970s, when Propper and colleagues[707,708] demonstrated that it could be given as a continuous syringe pump-driven subcutaneous infusion. This discovery and the schedule modifications of Pippard and colleagues[709] utterly changed the future of patients with thalassemia and other patients who required multiple transfusions. During the late 1970s and through the 1980s, several groups, particularly the large and well-managed Italian group of experts,[710,711,712,713] showed that the life span and cardiac disease–free life span of patients with thalassemia was remarkably improved by the administration of deferoxamine via the subcutaneous route. The concept was simple. Transferrin is totally saturated in iron overload, and thus the extra iron that leaks from loaded macrophages spills into the blood and creates a highly reactive plasma pool known as NTBI, a lethal reactive species first described by Hershko and colleagues[714,715] and productively investigated by Porter and colleagues.[716] NTBI attacks cell membranes, particularly the membranes of cardiac myocytes, and creates a flow of electrons that leaves the membranes badly oxidized. The continuous presence of deferoxamine in the plasma binds and removes NTBI, thus preventing further heart damage. However, the short half-life of deferoxamine leaves gaps in the plasma concentration of the drug unless the subcutaneous infusion is maintained 24 hours a day, 7 days a week. Such a schedule, although pharmacologically sensible, is totally unacceptable to the vast majority of patients. Furthermore, some patients experience inflamed nodules at the sites of subcutaneous injection (usually the fat pad of the anterior and lateral abdominal wall). The end result is a compromise in which patients and their physicians settle on a 12-hour subcutaneous infusion 5 nights a week at a dose of 20 to 40 mg/kg. Although such a schedule is reasonably well tolerated, adolescents dislike it not only because of the discomfort of the needle, but also because of the limitation of lifestyle. It is estimated that at least half of the patients "cheat" with regard to this abbreviated schedule and risk the development of cardiac symptoms of iron overload.

Orally Active Iron Chelators. The advent of orally active iron chelators has radically improved the quality of life of patients who undergo transfusion on a long-term basis, particularly those with severe β-thalassemia. However, both of the available drugs—deferiprone and deferasirox—have their limitations. Neither is as efficacious or as free of toxicity as deferoxamine, but freedom from a portable pump and an irritating subcutaneous needle has popularized both of them.

DEFERIPRONE. Deferiprone (see Fig. 21-30) was discovered by Huehns and colleagues[717] in the 1980s and licensed to Ciba Geigy, whose scientists discarded the drug because of lack of efficacy and evidence of rare but severe toxicity. Interest in the drug was then pursued in another London hospital, where it began to be introduced into clinical medicine.[718] This drug is approved by the Food and Drug Administration only for second-line therapy in the United States because of the inadequacy of its clinical trials in North America.

Although deferiprone is very specific for iron and readily penetrates cells, it is a bidentate chelator; therefore, three molecules of deferiprone are required to bind and eliminate one molecule of iron. The drug is promptly absorbed, but its half-life in plasma is less than 2 hours (better than deferoxamine but still very short). Therefore the drug must be administered frequently (every 8 hours is recommended, but that schedule leaves large gaps of inadequate plasma drug concentration), and high doses are required (a total of 75 to 100 mg/kg/day). Some patients (approximately half in a large recently published series in Thailand)[719] respond to the drug on the thrice-daily schedule with a decline in ferritin and in liver iron measured by MRI, but on average, the drug is barely effective at obtaining negative iron balance. This lack of effect on hepatic iron was also seen by the group in London that advanced the use of the drug most vociferously.[720] Some of the lack of efficacy may be due to compliance issues. It is very difficult to take any drug three times a day, let alone the preferable every 4 hours, but the latter schedule is probably required to maintain satisfactory plasma deferiprone concentrations that will eliminate toxic NTBI and achieve negative iron balance.

Deferiprone has a rare but lethal adverse effect. It can produce very severe neutropenia,[702] and the risk of that complication is present at any moment in the course of treatment. This potential adverse effect requires close supervision (in the United States, via weekly blood cell counts) and adds to the inconvenience and cost. Although Olivieri and her colleagues abandoned use of the drug because of its lack of efficacy and what they thought was toxicity expressed as excessive hepatic fibrosis,[702,721] the latter conclusion is uncertain. The observed fibrosis may be an artifact of sampling or simply due to lack of efficacy. Other serious adverse effects include severe joint (particularly knee) pain and swelling that seem to be prominent in South Asian patients[722] and rare drug-induced hepatitis.

In the past decade it has been suggested that deferiprone has a unique salutary effect on the removal of iron from the heart and siderotic heart disease.[723,724] Indeed, it has been claimed that iron is removed from the heart by deferiprone in the absence of any effect of the drug on liver iron stores. If that is true, no other chelator has such a beneficial effect. Proof of that unique capacity would require very careful comparative clinical trials that have not yet been performed. However, it is well worth exploring because such an effect would be most desirable. Unfortunately, the Canadian manufacturer of deferiprone has evinced little appetite for controlled clinical trials of any kind. It is likely that we will learn much more about this controversial drug from prospective trials.[724] It may well prove to be useful for compliant patients in jeopardy of iron-induced heart disease who cannot tolerate either deferoxamine or deferasirox.

DEFERASIROX. Deferasirox (Exjade; see Fig. 21-30) is a rationally designed drug related to a Russian discovery[725] and structurally related to the desferrithiocin class of chelators that was investigated very carefully by Ciba-Geigy and Bergeron and his colleagues in the 1980s and early 1990s.[726] Desferrithiocin was found to be highly effective but nephrotoxic even in the presence of high iron stores. Both deferasirox and desferrithiocin excrete iron entirely through the biliary system, and therefore only a blood level determination can be used to test compliance. Deferasirox was approved by the Food and Drug Administration in 2005. The drug's major attributes are that it is readily (if variably) absorbed,[725,727] it is a tridentate chelator highly specific for iron, and it has a half-life in plasma of more than 8 hours. Thus two molecules of the drug readily bind and eliminate one molecule of toxic NTBI. In addition, the drug persists for hours in the blood, providing excellent protection.[725] It is currently given as a single daily dose of between 20 and 40 mg/kg/day, but at the higher doses, absorption and therefore iron excretion are increasingly variable. Lower doses given twice a day might be more effective, but trials have not yet been performed to evaluate that possibility.

Deferasirox has been carefully investigated by its manufacturer. Many clinical trials have been performed in several iron-loading conditions.[728-730] The drug is effective in all of them, but variable absorption occurs in a substantial fraction of patients, for whom manipulation of dose and schedule is required. An increased level of creatinine is nearly universal, but significant nephrotoxicity has been an infrequent problem. However, gastrointestinal intolerance extending to bleeding duodenal and gastric ulcers has been reported. Rare hepatotoxicity can be severe. Dose and schedule adjustments and the liberal use of food during dosing should be explored in such patients.[731] A very large amount of literature describes clinical trials of deferasirox. Although it is several times as expensive as deferiprone, it is the best choice overall at this time. Data show that it prevents heart disease and other organ damage as well as deferoxamine, and the quality of life of patients who tolerate it well is far superior to that of patients who take either deferoxamine or deferiprone.[728,732]

Iron Overload in Persons with Thalassemia Intermedia. Prior to the advent of oral iron chelators, the management of persons with thalassemia intermedia was extremely difficult. Because of the effort to avoid transfusion, such patients experienced severe bony abnormalities, including short stature and gargoyle facies, as well as debilitating hepatosplenomegaly. In addition, as Musallam and others have pointed out, iron overload still remained a problem over time because of unimpeded iron absorption from the diet in the absence of a normal hepcidin response.[733,734]

The option of prescribing deferasirox has changed the calculus of the management of thalassemia intermedia. If serious growth disturbances occur, the patients should receive transfusions to suppress excess erythropoiesis and take deferasirox to prevent iron overload. Some investigators believe that transfusion and chelation should be offered during growth spurts and to induce sexual maturation. However, intermittent transfusion is a risky endeavor that can readily induce sensitization to minor blood groups, particularly in the United States where thalassemia is found so frequently in non-white persons but the vast majority of blood donors are white. The high incidence of sensitization in African Americans with sickle cell anemia who receive intermittent transfusions is an example of that problem.

Vitamin Supplementation

Ascorbic Acid. The role of ascorbic acid in iron metabolism and chelation therapy is complex and controversial.[735,736] Tissue deficiency of vitamin C often develops in patients with hemosiderosis because of accelerated catabolism; frank scurvy is documented in persons with marginal dietary intake.[737-740] Administration of vitamin C significantly augments iron excretion in response to deferoxamine, particularly in patients who have vitamin C deficiency. Serum iron and ferritin levels may also rise.[740-742] Ascorbic acid retards the rate of conversion of ferritin to hemosiderin[743,744] and presumably allows more iron to remain in a chelatable form. Unfortunately, ascorbic acid also enhances iron-mediated peroxidation of membrane lipids[745,746] and has been shown to increase iron-induced membrane damage in cultured myocardial cells.[747] It has also been observed that patients with iron overloads who are receiving vitamin C may experience cardiac dysfunction that is reversed when the supplementation is discontinued.[748,749]

Some investigators have suggested giving low doses of ascorbic acid (3 mg/kg) at the start of each subcutaneous infusion of deferoxamine. The chelator should be able to block the deleterious effects of ascorbic acid on lipid peroxidation of cellular organelles in vitro. Other clinicians avoid administering vitamin C to patients with iron overload and argue that iron depletion can be achieved without supplemental vitamin C. Patients with significant iron burdens should be cautioned against self-administration of substantial amounts of ascorbic acid because abrupt cardiac deterioration has been observed in this setting (Nienhuis AW, unpublished observations, 1990).

Vitamin E. Deficiency of vitamin E has been noted in many patients with thalassemia major who receive transfusions on a long-term basis.[750-754] Deficiency of vitamin E may contribute to hemolysis as a result of red blood cell membrane damage.[463,755] α-Tocopherol has long been considered to be a potent antioxidant that protects membrane lipids from attack by free radicals formed when excess iron is present. Deficiency in the neonatal period[756] or deficiency caused by malnutrition is associated with varying degrees of hemolysis. Hemolysis and the characteristic increased red blood cell susceptibility to in vitro hydrogen peroxide are readily reversed via the administration of supplemental vitamin E. Of interest, supplemental iron administration increases the hemolytic rate, even in patients with vitamin E deficiency who do not have thalassemia.[756] In patients with iron overload, supplemental vitamin E may lessen iron-mediated cellular toxicity. One study in experimental animals suggests that vitamin E may also inhibit deferoxamine-induced urinary iron excretion.[757] Although vitamin E is used clinically, the efficacy of this therapy remains to be demonstrated.

Folic Acid. Megaloblastic anemia, which is almost invariably due to folic acid deficiency, may occur in patients with severe β-thalassemia.[758-760] In contrast, vitamin B_{12} deficiency is extremely rare in patients with thalassemia.[760] Folic acid deficiency is thought to develop as a result of decreased absorption, low dietary intake, and the enormous demand of bone marrow expansion. Most patients benefit from daily folic acid administration (1 mg), although patients receiving adequate transfusions to suppress erythropoiesis and those living in countries where folic acid is added to many breads and cereals probably do not require supplementation.

Trace Metals. Trace metal deficiency associated with thalassemia or aggressive chelation therapy is not commonly observed.[735,761] Zinc deficiency (acrodermatitis enteropathica) has been reported in a patient receiving diethylenetriaminepentaacetic acid for chelation.[762] The reversible toxic effects seen with high-dose deferoxamine chelation may reflect trace metal deficiency or intracellular chelation of a trace metal. Newer techniques to analyze trace metal concentrations may reveal subtle deficiencies; yearly screening for zinc deficiency is appropriate, but supplementation is not usually required.

Allogeneic Bone Marrow Transplantation. Successful cure of β-thalassemia by bone marrow transplantation was first reported by Thomas and colleagues[763] in 1982. Subsequently, a number of centers have explored the use of this modality as definitive therapy for β-thalassemia. The most extensive published experience with bone marrow transplantation in β-thalassemia is that of Lucarelli and colleagues[764-768] in Italy. The results of their early attempts to use transplantation in this patient population were discouraging.[765] The preparative regimens used were often ineffective and associated with graft failure, toxicity, and high mortality. Their recent experience is considerably more promising.[768] Patients were analyzed to identify clinically important variables predictive of transplant outcome. The probability of survival was decreased in patients with poor chelation status, hepatomegaly (>2 cm), and portal fibrosis. The probability of event-free survival was reduced in the presence of hepatomegaly. Risk factors for hepatomegaly and portal fibrosis were used to divide patients into three classes: class 1, absence of both risk factors; class 2, one risk factor; and class 3, both risk factors. However, such classification of patients may be difficult to reproduce (i.e., hepatomegaly of ≤2 cm and a history of adherence to chelation therapy). The most recent data from Lucarelli for class 3 patients younger than 17 years who received human leukocyte antigen (HLA)-identical matched sibling donor transplants demonstrated significant improvement with the addition of hydroxyurea, azathioprine, and fludarabine to the previous regimen of cyclophosphamide and busulfan.[769] In the 33 patients treated with the new protocol (protocol 26), the survival rate increased to 93% and the rate of graft rejection decreased from 30% to 8%.[769] Adults treated with protocol 26 demonstrated an improved thalassemia-free survival rate of 62% to 67%, and transplant-related mortality was decreased but still significant at 27%, down from 37%.

One of the major reasons for failure of bone marrow transplantation in patients with thalassemia may be the unpredictable pharmacologic effects of the busulfan used in most preparative regimens. Hyperabsorption of the drug is associated with hepatic veno-occlusive disease and hypoabsorption with recurrent thalassemia. Improved control of busulfan levels during induction may provide better clinical results.[770] Whatever the event-free survival estimates, bone marrow transplantation is the only viable option for patients who cannot or refuse to adhere to a well-administered transfusion and chelation program.[771]

On the basis of available data, bone marrow transplantation may be recommended to patients receiving adequate chelation who have no evidence of liver disease. Many of these patients can be cured. Although most such patients are very young, age does not appear to be a significant variable in determining outcome. Chronic graft-versus-host disease is still a potential long-term complication of successful allogeneic transplantation. A current limitation to the general applicability of this therapy is the availability of a related, HLA-matched donor. Only one in four siblings on average will be HLA identical. Improved management of graft-versus-host disease and the development of technologies for bone marrow transplantation from unrelated donors may expand the pool of potential donors in the near future. Some encouraging results have recently been reported.[772] The use of cord blood stem cells may also extend the donor pool.[773,774]

Pharmacologic Manipulation of Hemoglobin F Synthesis. The interaction between β-thalassemia and genetic syndromes that increase γ-globin synthesis has illustrated how even small increases in γ-globin production lead to a significant improvement in the effectiveness of red blood cell production in patients with thalassemia. Although steady-state production of HbF is a genetically determined trait,[12] perturbations in erythropoiesis may be associated with an increased capacity for HbF synthesis. Treatment of experimental animals or patients with a variety of cytoreductive agents including 5-azacytidine (5-Aza), hydroxyurea, vinblastine, and cytosine arabinoside leads to an increase in production of HbF.[775-785] Although the precise mechanism of action of these drugs remains incompletely defined, the increased capacity for γ-globin synthesis appears to be linked to rapid erythroid regeneration. Consistent with this hypothesis, hematopoietic growth factors that promote the expansion and maturation of erythroid precursors, including erythropoietin,[786-788] interleukin-3,[787-789] and granulocyte-macrophage colony-stimulating factor,[789] have also been suggested to enhance HbF synthesis in primate models. Of particular interest is the observation that infants delivered of diabetic mothers exhibit a delayed switch from γ- to

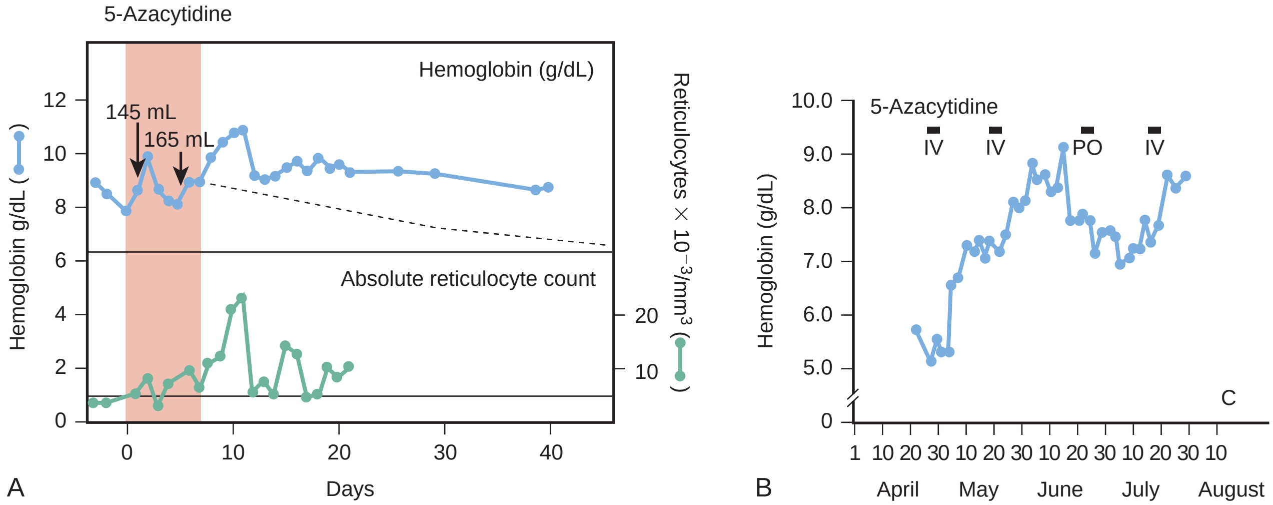

Figure 21-31 **A**, Effects of 5-azacytidine on erythropoiesis in a patient with severe homozygous β-thalassemia after a single administration of the drug by continuous infusion over a period of 7 days. Two small blood transfusions were administered on days 2 and 5. The *dashed line* indicates the projected hemoglobin concentration and reticulocyte count in this patient without treatment based on clinical records. **B**, Effects of sequential courses of treatment with 5-azacytidine in a patient with β-thalassemia who had severe cardiomyopathy and alloimmunization. *(**A**, Modified from information appearing in Ley TJ, DeSimone J, Anagnou NP, et al: 5-Azacytidine selectively increases gamma-globin synthesis in a patient with beta thalassemia.* N Engl J Med *307:1469–1475, 1982. **B**, From Dunbar C, Travis W, Kan YW, et al: 5-Azacytidine treatment in a beta zero-thalassaemic patient unable to be transfused due to multiple alloantibodies.* Br J Haematol *72:467–468, 1989.)*

β-globin.[790] Levels of butyric acid derivatives are elevated in the serum of these mothers and their infants before birth. Similarly, patients with metabolic disorders associated with increased levels of short-chain fatty acids also have elevated HbF levels.[791] Infusions of sodium butyrate or α-aminobutyric acid into fetal sheep markedly delay the perinatal switch,[792] whereas infusions in primates lead to activation of the γ gene (McDonagh KT, Bodine DM, and Nienhuis AW, unpublished observations).[793,794] It has been proposed that butyrate, propionate, or the metabolite acetate promotes increased γ-globin expression by acetylation of histones and alteration of chromatin structure, but other mechanisms cannot be excluded.[795,796] A flurry of articles have described the results of treatment of patients who have sickle cell anemia with butyrate or its derivatives.[797-802] One patient[798] had a sustained increase in hemoglobin, and healing of leg ulcers without an increment in circulating hemoglobin has also been observed.[801] A recent report cited a sustained increase in HbF in persons with sickle cell anemia.[803,804] Caution must be exercised, however, because high doses of butyrate are associated with neurotoxicity in simians.[805]

The most extensive experience with pharmacologic manipulation of HbF synthesis in patients has involved administration of hydroxyurea to patients with sickle cell disease (see Chapter 20).[781,806-810] In this population, the majority of patients appear to respond to the drug with a twofold or greater increase in HbF levels over their baseline. In many patients, HbF levels between 10% to 15% of total hemoglobin are seen. This increase reflects both augmented production and enhanced survival of cells that contain HbF. The clinical results in patients with sickle cell anemia are impressive, as described in Chapter 20. However, the results in patients with thalassemia have shown mixed results to date.[783,811] Of note, almost all studies performed in patients with thalassemia have either been case-control or cohort studies and variable end points have been used, confounding the ability to compare various studies.[811] However, it should be noted that hydroxyurea does show some promise in select patients with thalassemia.

A response to 5-Aza has been seen in several patients with thalassemia[776,812,813] (Fig. 21-31). The dramatic increases in HbF levels associated with administration of this drug may result from a combination of cytotoxicity and inhibition of postsynthetic methylation of DNA.[813-817] Global demethylation of DNA, including the γ-globin gene, is observed after the administration of 5-Aza. Despite its effectiveness,[811] the use of 5-Aza in the treatment of hemoglobinopathies has been limited by concerns about its known carcinogenic potential,[818-820] as well as the demonstrated effectiveness and safety of current treatment strategies involving transfusion and chelation. Because response to the drug is short-lived, long-term therapy would be required.

As previously discussed, the recent mechanistic insight gained into the regulation of HbF production through human genetic studies suggests that targeted and mechanism-based approaches to induce HbF may be developed in the coming years. In particular, targeting of regulators of this process such as BCL11A, KLF1/EKLF, or MYB holds promise for induction of HbF in patients.[821] Either direct targeting of these molecules, modulation of their cofactors that modify chromatin, or disruption of their activity at specific chromatin interaction sites may serve as valuable approaches for HbF induction.

Gene Therapy. As a result of advances in molecular biology, treatment of hematologic disease through the introduction of new genetic material into bone marrow stem cells is a goal for the foreseeable future.[822-825] Application of somatic gene therapy to the treatment of hematologic diseases requires improved efficiency of gene delivery, regulated and sustained expression of the introduced genes, and biologic studies demonstrating expression of the foreign gene. Although active research is ongoing, experimental shortcomings in all these aspects presently preclude the use of gene therapy for the management of thalassemia or sickle cell anemia.

Correction of thalassemia by gene transfer will necessitate the introduction of a normal β-globin gene into hematopoietic stem cells.[822-824] Experimental studies in mice have demonstrated that retroviral vectors are capable of transferring foreign sequences to hematopoietic stem cells.[826,827] Expression of transferred genes has been more problematic but has been improved with use of a new vector containing a portion of the LCR, which has led to 17% to 33% HbF.[828] The efficiency with which primate (or human) stem cells are infected by retroviral vectors appears to be lower than that observed in murine cells. Nonetheless, transfer of foreign sequences to long-term repopulating hematopoietic cells of primates and humans has been demonstrated.[829]

For treatment of β-thalassemia (or sickle cell anemia), it will be necessary to express the transferred gene at high levels in erythroid cells. This task has been a challenge in the field, but vectors that incorporate elements of the LCR have recently been generated. Lentiviral vectors containing such elements have been constructed. Indeed, it has become possible to achieve long-term correction of both sickle cell anemia and β-thalassemia in mouse models with these viruses.[830-832] In addition, a phase I human gene therapy trial has been initiated, and the first patient treated with use of such approaches has been reported.[833] However, concerns exist about the limited clonality of hematopoiesis observed in this patient and an insertion of the lentiviral genome upstream of the *HMGA2* oncogene that is observed in this dominant clone. In addition, it should be noted that the patient has had a high level of HbF expression after the introduction of the corrected cells, bringing into question whether the gene correction itself was sufficient for the independence from transfusion observed.

Interaction of Thalassemia with Globin Structural Variants

In geographic areas in which thalassemia mutations and structural variants of α- and β-globin genes are both commonly seen (such as Africa and Southeast Asia), compound heterozygotes with a thalassemia mutation and a structural variant are common.[1] In such double heterozygotes, disease may be more or less severe than that seen in persons who are heterozygous for only the structural variant. For example, heterozygotes for a β^S gene have 30% to 45% HbS and are usually clinically healthy, whereas patients with a β^S gene and a β-thalassemia mutation (in the *trans* β gene) have 60% to 95% HbS and may have a severe sickling disorder. Persons with a β^S gene and α-thalassemia trait generally have less HbS than those with sickle trait[834,835] and are asymptomatic.[836,837] The interaction of α- and β-thalassemia mutations and the HPFH mutations with the β^S gene are described in detail in Chapter 20.

Hemoglobin E–β-Thalassemia

HbE–β-thalassemia is particularly common in Southeast Asia, where as many as 4000 to 5000 patients may reside in Thailand alone.[838,839] As a result of immigration from Southeast Asia, HbE–β-thalassemia is now a commonly encountered form of transfusion-dependent thalassemia in certain areas of the United States.[840,841] Double heterozygotes not receiving transfusions have hemoglobin levels of 2.3 to 7 g/dL, depending primarily on the output of the β-thalassemia gene. Because α-thalassemia is common in Southeast Asia, more complex phenotypes may be observed.[842] Nucleated red blood cells are found on the peripheral blood smear, whereas they are absent in patients homozygous for β^E. HbE and HbA_2 account for 50% to 70% of the total hemoglobin (5% HbA_2 by HPLC).[841,843] Small quantities of HbA are found in association with a β^+-thalassemia gene. Patients with HbE–β-thalassemia usually require transfusions and exhibit the clinical features of thalassemia major. In areas where intensive treatment is unavailable, the disease resembles classic thalassemia major, with patients exhibiting massive hepatosplenomegaly, hypersplenism, severe skeletal disease, and death from infection in childhood. Iron loading occurs as a result of either transfusion or enhanced intestinal absorption.[844] Proper treatment is the same as that recommended for thalassemia major or intermedia, depending on the requirement for regular blood transfusion. Recent work has also suggested that there are different compensatory responses in HbE–β-thalassemia as patients get older, which may have important implications in the management of this disease.[845] These alterations in the compensatory responses of older patients are also likely to be applicable to patients with other forms of β-thalassemia.

Hemoglobin C–β-Thalassemia

The β^C gene, which encodes a variant β chain with a lysine→glutamic acid substitution at position 6,[846] is common in blacks of West African origin. The only hematologic consequence of simple heterozygosity for the β^C gene is increased target cells on the peripheral smear. Double heterozygotes with a β^C gene and β-thalassemia genes exhibit moderately severe hemolytic anemia with splenomegaly. The peripheral blood smear reveals hypochromia and microcytosis with many target cells. Hemoglobin C accounts for 65% to 95% of the total hemoglobin, depending on whether the thalassemia mutation is of the β^+ or β^0 variety. In the black population the disease is generally mild because of the prevalence of mild β-thalassemia genes (discussed earlier),[510] whereas in Italian,[847] North African,[848] and Turkish patients,[849] the disease is more severe, particularly in those who have a β^0-thalassemia mutation.

Thalassemic Hemoglobinopathies

As discussed in detail in earlier sections, several variant polypeptides can be described as thalassemic hemoglobinopathies. With the exception of HbE and the elongated α-chain variants, these mutations are very uncommon. Interest in these mutations arises from the unique mechanisms by which they produce the thalassemia phenotype.[258,850] The most common thalassemic hemoglobinopathy is HbE disease.

Hemoglobin E Disease. As described earlier, the β^E mutation activates a cryptic splice site in exon 1 (see Fig. 21-9). Because the correct splice site is less efficiently used, production of functional β-globin mRNA that codes for the variant decreases.[168] The incidence of the β^E gene is extraordinarily high in some populations (≈30% in Laos, Cambodia, and Thailand).[838,851] The occurrence of the gene in immigrants from Southeast Asia to the United States reflects these origins.[841]

In the heterozygous form, patients are largely asymptomatic with a hemoglobin level of 12 g/dL or greater, no reticulocytosis, an MCV of 74 ± 10.6 μm^3, and an MCH of 25 ± 2.5 pg. The peripheral blood smear is distinguished by mild microcytosis and occasional target cells. Hemoglobin electrophoresis reveals HbE comigrating with HbA_2 in the range of 19% to 34%. The α to ββ biosynthetic ratio is usually 0.8 or greater, hence the mild nature of HbE trait.

Patients with homozygous HbE disease are also asymptomatic.[839,843] The hemoglobin level is rarely less than 10 g/dL, and significant reticulocytosis is uncommon. The red blood cells, however, are markedly microcytic (MCV of 50 to 66 μm^3) and hypochromic (MCH of 20.1 pg). Target cells and occasional coarse stippling are evident on the smear. HbE accounts for 90% or more of the total hemoglobin, with varying levels of HbF.

The differential diagnosis of microcytic anemia in the Southeast Asian population initially requires the exclusion of iron deficiency. When present, electrophoresis will identify HbE. However, its level may be diminished in the presence of α-thalassemia or iron deficiency because the affinity of normal β chains for α-globin exceeds that of β^E chains. Interaction of α-thalassemia mutations with the β^E gene is usually seen because of the high incidence of each in the Southeast Asian population.[842]

PRENATAL DIAGNOSIS OF THALASSEMIA

The morbidity and mortality associated with severe forms of thalassemia prompted efforts to develop effective prenatal diagnosis more than 2 decades ago. For the vast majority of β-thalassemias, for which point mutations are usually responsible, early efforts focused on determination of globin chain synthesis in fetal blood cells obtained by aspiration of placental vessels or direct visualization of fetal vessels.[852-856] The risk associated with fetal blood sampling at 18 to 20 weeks' gestation proved to be acceptably low when performed by experienced personnel (fetal loss rate of ≈3%; error rate of <0.5%) such that between 1975 and 1985, more than 7900 pregnancies were studied.[855] As molecular methods and the knowledge of mutations leading to thalassemia improved, strategies for prenatal detection of these conditions evolved.

Successful prenatal diagnosis of α-thalassemia of the hydrops fetalis variety by solution hybridization methods to detect deficiency of α-globin genes in amniotic fluid cell DNA was first reported by Kan and colleagues[856] in 1975. Southern blot analysis rapidly supplanted this approach for the detection of gene deletion in either the α- or β-thalassemias.[857,858] Detection of mutations in DNA rapidly became the preferred strategy for prenatal diagnosis as mutations became defined in the β-thalassemias.[3] The introduction of polymerase chain reaction methods further facilitated the detection of mutations and also permitted the use of nonradioactive tests.[859] Coupled with chorionic villus biopsy, accurate and safe diagnosis can be accomplished within the first trimester of pregnancy. More recently, noninvasive methods consisting of examination of fetal erythrocytes in maternal plasma[860] and analysis of nucleic acids in maternal plasma[861] have provided promise for detection of severe thalassemia

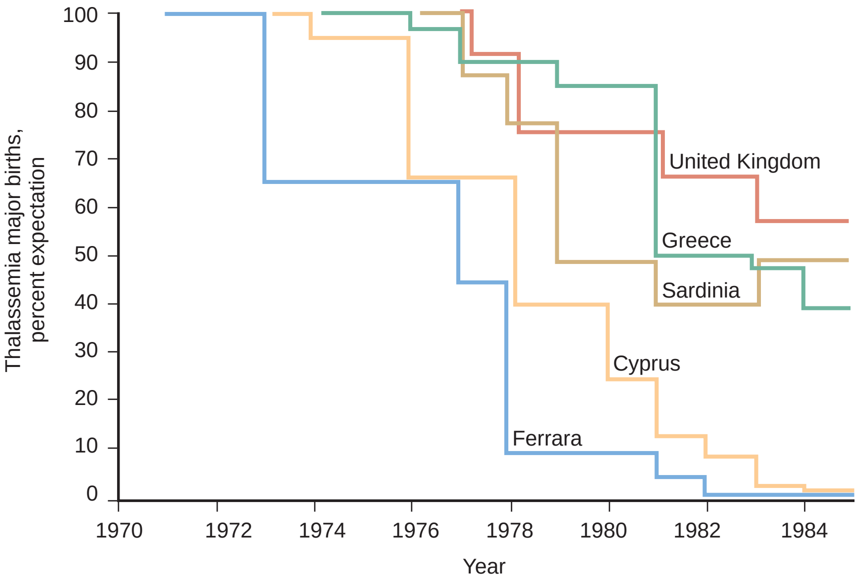

Figure 21-32 A decrease in the birth rate of infants with thalassemia major in Great Britain and several Mediterranean regions after the introduction of effective prenatal diagnosis. *(Modified from Modell B, Bulyzhenkov V: Distribution and control of some genetic disorders.* World Health Stat Q *41:209–218, 1988.)*

syndromes, without risk to the fetus. The recent development of such noninvasive prenatal genetic testing approaches, enabled by newer sequencing approaches, holds promise for their implementation for prenatal diagnosis of severe thalassemia syndromes.[862,863]

Besides molecular biology, prenatal diagnosis of thalassemia has relied on identification of couples at risk, widespread public education, and genetic counseling. In countries in which the incidence of β-thalassemia is high and the burden of disease to the overall population great, such as on the island of Sardinia and in Greece, intensive prevention programs have been established and have proved to be extraordinarily successful. For example, the birth of children with β-thalassemia in these areas has been reduced by more than 90% in recent years[864-869] (Fig. 21-32). These results represent major achievements in the prevention of genetic disease and paradigms for other disorders.[†]
